The conversion of phenylalanine to tyrosine is catalyzed by the enzyme phenylalanine hydroxylase (PAH). This enzyme requires a cofactor known as tetrahydrobiopterin ( $\text{BH}_4$ ). Confirmed hyperphenylalaninemia in the infant is due to a primary or secondary ( $\text{BH}_4$  deficiency) reduction in PAH activity. As in many inherited disorders, the detection of a primary metabolite abnormality, in this case hyperphenylalaninemia, requires the consideration of a spectrum of possible genetic causes before proper diagnosis and management are possible. The failure to appreciate that several disorders as well as benign metabolic conditions can cause hyperphenylalaninemia was a serious early problem in newborn metabolic screening (1).

The causes of hyperphenylalaninemia (27) include

1. Transient hyperphenylalaninemia
2. Persistent non-PKU hyperphenylalaninemia
3. PKU (PAH deficiency)
4. Three disorders causing defective  $\text{BH}_4$  synthesis
5. Impaired recycling of  $\text{BH}_4$  due to dihydropteridine reductase (DHPR) deficiency

The phenylalanine concentration in newborn blood is normally less than  $120\ \mu\text{M}$  ( $2\ \text{mg/dL}$ ). The screening result is considered to be positive when the phenylalanine concentration exceeds  $120$  or  $240\ \mu\text{M}$  ( $4\ \text{mg/dL}$ ), depending on which cutoff the screening laboratory uses. With MS/MS technology, many laboratories also consider the phenylalanine:tyrosine ratio, which is increased to five-fold or greater in PKU. Positive screening results should be promptly followed by confirmatory tests of blood and urine. Complete plasma amino acid analysis can confirm the elevated phenylalanine and reduced tyrosine concentrations and rule out the presence of other amino acid abnormalities. The diagnosis of PKU is generally assigned when (i) the plasma phenylalanine concentration is  $>400\ \mu\text{M}$  ( $>6.5\ \text{mg/dL}$ ) in confirmatory follow-up tests while the infant is ingesting a normal diet, (ii) the tyrosine concentration is normal or reduced, and (iii) analyses of pterins in urine and DHPR activity in blood yield normal results (see later). When these criteria are met, a phenylalanine-restricted diet should be instituted promptly in order to prevent the cognitive impairment seen in untreated PKU. If the confirmatory phenylalanine level is  $120\text{--}360\ \mu\text{M}$  ( $2\text{--}6\ \text{mg/dL}$ ), the infant is likely to have mild hyperphenylalaninemia and a normal diet may be continued (28).

$\text{BH}_4$  is the cofactor for PAH. About 30–40% of patients with PKU, usually the mild form, are responsive to pharmacologic amounts of  $\text{BH}_4$  in that, when treated with this cofactor (available as the drug “Kuvan”), the phenylalanine level decreases by 30% or more. In rare instances this therapy may be sufficient to control the blood phenylalanine level without diet. Much more frequently diet is still required but with a reduction in stringency (29). Certain PAH mutations seem especially likely to be associated with  $\text{BH}_4$  responsiveness (30,31).

Primary hyperphenylalaninemia is due to PKU produced by a deficiency of PAH, whereas secondary hyperphenylalaninemia is caused by a deficiency of  $\text{BH}_4$ . The  $\text{BH}_4$ -deficiency disorders are characterized by progressive neurological deterioration despite dietary phenylalanine restriction and control of the hyperphenylalaninemia (32). Thus, they must be distinguished from PKU.  $\text{BH}_4$  is required as a cofactor not only for PAH but also for tyrosine and tryptophan hydroxylases. Consequently, in  $\text{BH}_4$  deficiency the conversions of tyrosine to dihydroxyphenylalanine (DOPA) and tryptophan to 5-hydroxytryptophan are also impaired, disrupting synthesis of the neurotransmitters dopamine and serotonin, respectively. A number of patients and families with  $\text{BH}_4$  deficiency have been collected and studied. The genes for these enzymes have been cloned and several mutations characterized (32). Therapy consists of supplementation with  $\text{BH}_4$  and the neurotransmitter precursors DOPA and 5-hydroxytryptophan. Because the degrees of hyperphenylalaninemia in PKU and  $\text{BH}_4$  deficiency are similar during the newborn period, accurate diagnosis requires an *in vivo* or *in vitro* test or a combination of these two methods (32,33). In the United States, the usual method for distinguishing PKU from  $\text{BH}_4$  deficiency is to collect filter-paper specimens of blood and urine at confirmatory examination. The blood is assayed for DHPR, the recycling enzyme for  $\text{BH}_4$ , and the urine is tested for pterins. Reduction in DHPR suggests the DHPR-deficiency form of  $\text{BH}_4$  deficiency, while an abnormal urine pterin pattern suggests a biopterin synthesis defect. In Europe, loading the hyperphenylalaninemic neonate with  $\text{BH}_4$  at a dose of  $20\ \text{mg/kg}$  is used to distinguish  $\text{BH}_4$  deficiency and  $\text{BH}_4$ -responsive PKU from PKU that is nonresponsive to  $\text{BH}_4$  (28). In  $\text{BH}_4$  deficiency,  $\text{BH}_4$  administration results in a reduction in the phenylalanine level to almost normality and in  $\text{BH}_4$ -responsive PKU the phenylalanine level decreases significantly, whereas in PKU that does not respond to  $\text{BH}_4$ , the phenylalanine level is unchanged. In the United States, the  $\text{BH}_4$  challenge is usually not given until or close to 2 years of age.

Hyperphenylalaninemia not due to either PKU or  $\text{BH}_4$  deficiency may be transient and disappear within the first months of life (33). This requires no specific therapy and is usually mild. In some instances, the hyperphenylalaninemia is accompanied by transient hyper-tyrosinemia. Other infants, however, will have mild hyperphenylalaninemia that persists and is accompanied

by a normal tyrosine concentration. This non-PKU mild hyperphenylalaninemia seems to be benign. A study from Germany evaluated 31 adolescent and young adult individuals with non-PKU mild hyperphenylalaninemia whose natural blood phenylalanine levels were no greater than 600  $\mu\text{M}$  (10 mg/dL) and who were never treated. All had normal IQs, normal educational experiences, and no changes in the cerebral white matter on examination by MRI (34).

Maternal PKU is not identified by neonatal screening but is an unintended consequence of screening and the prevention of mental retardation from PKU. When these women later reproduce, their pregnancies are at high risk to the nonphenylketonuric fetus, with potential consequences that include mental retardation, microcephaly, congenital heart disease, and intrauterine growth retardation (35). Data from the Maternal PKU Collaborative Study, however, indicate that diet begun before conception or within the first six gestational weeks with maintenance of good metabolic control, specifically blood phenylalanine concentrations in the range of 120–360  $\mu\text{M}$  (2–6 mg/dL), results in good offspring outcome (36). In contrast with maternal PKU, data from the same study indicated that women with mild hyperphenylalaninemia whose natural blood phenylalanine concentrations were no greater than 600  $\mu\text{M}$  (10 mg/dL) and who remained untreated during pregnancy also had normal offspring, suggesting that maternal non-PKU mild hyperphenylalaninemia is benign (37). Offspring from mothers with PKU rarely have PKU themselves but all such offspring must be carefully tested for PKU to be certain that they are non-hyperphenylalaninemic. Breast feeding can be practiced by the mother with PKU and will not raise the phenylalanine level of the baby even if the mother discontinues the diet after giving birth (38).

## 27.5.2 Galactosemia

At least three disorders of galactose metabolism are detectable in newborn screening. They are appropriate targets for newborn screening because of the need for early intervention. The most frequent of these disorders is classical galactosemia due to deficiency of GALT, an enzyme that is normally present in most tissues, including liver, skin fibroblasts, and red blood cells (39). The untreated clinical course is characterized in the neonate by failure to thrive, jaundice, hepatomegaly, and often death from sepsis, usually due to *Escherichia coli*. Untreated infants who survive suffer from developmental retardation, cirrhosis, and cataracts. Early diagnosis can lead to treatment that prevents neonatal death. Even when the infant is obviously ill, the correct clinical diagnosis of this rare inborn error of metabolism is often not made. Although newborn screening and early treatment are clearly needed, they have not prevented later complications that include reduced cognition, dyspraxia, neurological abnormalities, and ovarian failure (40).

Several variants of galactosemia have been described (41,42). In the African-American variant, associated with the S135L mutant GALT allele, low but detectable levels of GALT activity are present in the liver and intestinal mucosa but not in erythrocytes, and the clinical course is usually relatively mild. Variants such as Rennes and Indiana may be associated with some or all of the serious clinical abnormalities. The Duarte variant, associated with the N314D mutant allele, is characterized by diminished erythrocyte GALT activity and altered electrophoretic mobility of the enzyme without clinical abnormalities. This variant is probably benign (43).

The two other galactose metabolic disorders are galactokinase deficiency and uridine diphosphate galactose-4-epimerase deficiency. These are much less frequent than galactosemia. Galactokinase deficiency leads to cataract formation in older untreated patients without other evidence of galactose toxicity, whereas epimerase deficiency is usually benign. Treatment of galactosemia or galactokinase deficiency aims at rigorous exclusion of galactose from the diet and, if instituted early, is completely effective in preventing or reversing the potentially lethal neonatal abnormalities (44). Despite successful treatment in infancy, the majority of classic galactosemia patients in all countries nonetheless go on to experience serious long-term complications in cognitive, neurologic, and in females, ovarian functions (41).

## 27.5.3 Homocystinuria (Cystathionine $\beta$ -Synthase Deficiency)

Increased methionine in newborn screening leads to identification of homocystinuria due to CBS deficiency. This can result in early treatment that prevents serious phenotypic abnormalities. CBS is responsible for the condensation of L-homocysteine and L-serine to form cystathionine, using pyridoxal-5-phosphate (vitamin B<sub>6</sub>) as cofactor. A deficiency of CBS produces increased homocysteine and secondary hypermethioninemia. Homocystinuria is inherited as an autosomal recessive condition and may result in clinical abnormalities that include mental retardation, ectopia lentis, thromboembolism affecting large and small arteries, and skeletal abnormalities. Early treatment has been effective in preventing the clinical consequences (45). Treatment includes a diet that is restricted in methionine and supplemented with cystine and, in those patients responsive to pyridoxine, pharmacological doses of the vitamin. Treatment with orally administered betaine has also proved effective in controlling the level of homocystinemia in many patients (46). Some cases of homocystinuria have escaped detection by newborn screening. This has raised concerns about a possible slow rise in blood methionine (22). The blood methionine concentration may not exceed normal (67  $\mu\text{M}$ ) until after the first week of life in affected infants. Lowering the cutoff level for methionine in screening from the usual 134  $\mu\text{M}$

to 67  $\mu\text{M}$  has resulted in detecting cases screened before 48 h of age who otherwise would have been missed (22). Conversely, later in the neonatal period normal infants may have methionine elevations to 170  $\mu\text{M}$  or greater that are usually transient and related to a high-protein diet. Other causes of hypermethioninemia include liver disease, tyrosinemia (see later), and methionine adenosyltransferase I/III deficiency (47), as well as glycine N-methyltransferase deficiency (48,49). Hyperhomocysteinemia and increased urinary homocystine also result from defects in the metabolism of folates and cobalamins that are required for the methylation of homocysteine to methionine (50). In these conditions, the concentration of methionine is low or normal, even though the concentrations of homocysteine and related compounds are increased. Consequently, these remethylation disorders escape detection in newborn screening that is limited to detecting increased methionine.

#### 27.5.4 Maple Syrup Urine Disease

Increased leucine in newborn screening is the marker for MSUD. This disorder results from deficient activity of one of the enzymes involved in the oxidative decarboxylation of the  $\alpha$ -keto acid derivatives of the branched-chain amino acids leucine, isoleucine, and valine (51). The newborn with MSUD is clinically normal at birth but during the first week begins to feed poorly, rapidly followed by vomiting, lethargy, muscular hypertonicity, seizures, coma, and death. Laboratory features include metabolic acidosis and, often, hypoglycemia. The well-known urinary odor of maple syrup may not be present in the newborn. Acute therapy includes elimination of protein intake, high-calorie intravenous fluids, and enteral feeding of a special amino acid elemental formula that does not include leucine (52,53). This anabolic regimen after identification by newborn screening has resulted in the prevention of clinical disease (52) or rapid recovery once clinical symptoms occur (53) and good clinical outcome. Hemodialysis to quickly reduce blood leucine may be required in infants who are critically ill. Several variants of MSUD with milder clinical and biochemical abnormalities have been described (51). A transient elevation of the blood leucine concentration (rarely greater than 6 mg/dL) occurs in 0.1–0.2% of newborns screened.

#### 27.5.5 Tyrosinemia

Tyrosine is measured in all newborn screening programs. The major reason for including the measurement of tyrosine was to identify tyrosinemia I (hepatorenal tyrosinemia), the most frequent of the tyrosinemias. It is now apparent that neonates with tyrosinemia I almost always have normal or near-normal levels of tyrosine in newborn screening and therefore cannot be reliably detected in this manner. In 2002, a method for measuring the

metabolite succinylacetone in the screening blood specimen was developed (54). An elevation of this metabolite is pathognomonic of tyrosinemia I. Consequently, many newborn screening programs have added a succinylacetone test to the screening profile. The inclusion of succinylacetone analysis into routine analysis of acylcarnitines and amino acids allows for rapid and cost-effective screening for tyrosinemia I, with the potential to eliminate the risk of false-negative results. Most screening programs continue to measure tyrosine, however, in order to detect the two other tyrosinemia metabolic disorders, tyrosinemia II and tyrosinemia III. Transient tyrosinemia is prevalent in newborn screening. In at least 1–2% of infants, the blood tyrosine concentration exceeds 5 mg/dL at some time during the first 3 months of life. The frequency is even higher in premature babies. Transient tyrosinemia usually disappears spontaneously within a few weeks; its disappearance can often be promoted by administering vitamin C or with a protein-restricted diet (55).

Tyrosinemia I is an autosomal recessively inherited disorder in which the primary enzyme defect is deficiency of fumarylacetoacetate hydrolase, the final enzyme in the degradation of tyrosine (55). The prevalence of this disorder is unusually high in the Quebec province of Canada. The clinical abnormalities are usually evident within the first 6 months of life but can be detected in a neonate. These abnormalities include hepatomegaly with liver disease, often accompanied by ascites, and kidney disease characterized by the renal Fanconi syndrome. Confirmatory plasma amino acid analysis usually reveals increased tyrosine and methionine, although the amino acid levels in the presymptomatic neonate may be normal. Confirmatory testing should include the measurement of succinylacetone in blood and urine. The presence of elevated succinylacetone confirms the diagnosis. Dietary restriction of phenylalanine and tyrosine has not prevented progression of liver disease, and approximately one-third of dietary-treated patients develop hepatocellular carcinoma, often in childhood. Thus, liver transplantation was previously the only effective option for these patients. Fortunately, a specific therapy known as Orfadin (NTBC) is now available and is the therapy of choice. This therapy has been highly effective in controlling the accumulation of succinylacetone and reversing or preventing the liver disease (56). Liver transplantation is still an option, however, for patients with chronic liver disease in whom the therapy may be too late to prevent hepatocellular carcinoma.

Tyrosinemia II, also called the Richner–Hanhart syndrome, results from deficiency of hepatic tyrosine aminotransferase and has been reported in fewer than 100 cases (55). Blood tyrosine concentrations are 20–50 mg/dL on an unrestricted diet. Mental retardation is usually present, while hepatic and renal involvement is absent. Other clinical abnormalities include keratitis and palmar hyperkeratosis. This disorder does produce elevated blood tyrosine within the first days of life and has been detected by

routine newborn screening using MS/MS (57). Tyrosinemia III may also be detected by elevated tyrosine in newborn screening. This appears to be a benign condition (55).

Other inherited disorders may lead to a secondary elevation of the blood tyrosine concentration when the infant is ill. Notable among these are galactosemia and hereditary fructose intolerance. Both of these disorders elevate blood tyrosine concentration by deleterious effects on hepatic metabolism. Because liver disease of any cause can elevate the blood tyrosine concentration, detecting either tyrosinemia or hypermethioninemia may simply signal the presence of liver disease.

### 27.5.6 Biotinidase Deficiency

Biotinidase deficiency can be detected in newborn screening, and if treated with pharmacological doses of biotin, the otherwise serious abnormalities are prevented. Biotin is a water-soluble vitamin that acts as a coenzyme for four carboxylases required for the catabolism of two intermediary organic acids in branched-chain amino acid metabolism, for the first step of gluconeogenesis, and for the synthesis of fatty acids (7). These carboxylases are normally activated by covalent attachment of biotin. Proteolytic degradation of these carboxylases releases a biotin-containing product known as biocytin (biotinyl-lysine). Normally, biotinidase hydrolytically releases biotin from biocytin, allowing some of the biotin to be recycled. In biotinidase deficiency, the biotin is not released, leading to intracellular deficiency of biotin.

Biotinidase deficiency is inherited in an autosomal recessive pattern (7). Most symptomatic children have profound biotinidase deficiency (less than 10% of the normal mean for serum activity). The frequency of the deficiency in newborns has varied among reported studies of newborn screening results, but the incidence of the profound deficiency is estimated at about 1:112,000 and the incidence of partial deficiency at about 1:129,000, for a combined incidence of 1:60,000 (7). Confirmation of diagnosis is by assay of serum biotinidase activity. Mutant alleles of the biotinidase gene have been identified. Although genotype–phenotype correlations have not been firmly established (7), one mutation, c.1489C>T (p.Pro497Ser), is frequent in profound deficiency and another mutation, c.1330G>C (p.Asp444His), has always linked to partial deficiency (57). Biotinidase-deficient persons may become biotin deficient during infancy or early childhood (8). Signs and symptoms are mainly neurological and cutaneous and include seizures, ataxia, hypotonia, developmental delay, hearing loss, skin rash, and alopecia. Symptomatic individuals with profound deficiency usually also manifest an organic aciduria, metabolic acidosis, and mild hyperammonemia (57). The reversible symptoms of biotinidase deficiency (seizures, rash, and alopecia) have consistently responded to treatment with biotin, and newborn screening identification and treatment prevent all of the symptoms. Importantly,

biotinidase deficiency must be differentiated from holocarboxylase deficiency with which it shares many clinical and biochemical features (8).

### 27.5.7 Urea Cycle Disorders

Routine neonatal screening currently can identify three of the six urea cycle disorders. These include citrullinemia and argininosuccinic acidemia, both identified by increased citrulline in newborn screening, and arginase deficiency, identified by increased arginine. Detailed discussion of these disorders can be found elsewhere in this book (Chapter 92). The urea cycle is responsible for metabolizing ammonia released during the turnover of amino acids, which results from the ingestion and endogenous turnover of protein. A deficiency in any of the six urea cycle enzymes blocks this metabolic pathway and produces hyperammonemia as well as a reduction in urea. The hyperammonemia is extremely toxic to the brain and can produce life-threatening cerebral edema. Citrullinemia (argininosuccinic synthetase deficiency) and argininosuccinic acidemia (argininosuccinic lyase deficiency) may present acutely in the neonate or have a later onset with a chronic course. Mild citrullinemia has been reported as benign (59), and argininosuccinic acidemia may also have a relatively benign or completely benign phenotype (60,61). Arginase deficiency usually has a clinical phenotype very different from the other urea cycle disorders in that the hyperammonemia is milder and the patients have a chronic neurologic picture characterized by spastic diplegia and developmental delay. A rare patient with arginase deficiency, however, has been described with an acute lethal neonatal course (62).

A second form of citrullinemia has recently been reported. This form, called citrullinemia type II or citrin deficiency, is also identified in neonatal screening by increased citrulline in the newborn specimen. The primary defect is in citrin, a mitochondrial carrier protein primarily located in the liver. The most frequent neonatal feature has been intrahepatic cholestasis that often results in a secondary increase in galactose, methionine, phenylalanine, and/or tyrosine, elevations that may also be detected in newborn screening (63).

Several newborn screening programs also screen for decreased citrulline. This allows for the identification of the proximal urea cycle disorders NAGS deficiency, CPS deficiency, and OTC deficiency (14). These three disorders can have a life-threatening neonatal presentation with profound hyperammonemia and, if so, require immediate and dramatic therapy.

Treatment of the urea cycle disorders requires immediate measures for the acute hyperammonemic neonatal course. These include discontinuation of protein intake and administration of intravenous fluids with very high caloric value. In addition, “scavenger” medication such as sodium benzoate and sodium phenylacetate are administered to aid in waste nitrogen removal. Hemodialysis

may be required. The chronic therapeutic regimen consists of a low-protein diet supplemented by the organic acid medications.

### 27.5.8 Organic Acid Disorders

Many of the organic acid disorders may also be detected by expanded neonatal screening using MS/MS technology. Identification is on the basis of an increased concentration of an acylcarnitine. The organic acidemias are a heterogeneous group of disorders and are described in greater detail in Chapter 97 of this book. Most are defects in amino acid metabolism but, in contrast with the amino acid disorders, are at a step in the metabolic pathway where an organic acid derivative of the amino acid is normally converted to another organic acid. The defect results in an increased concentration of the unconverted organic acid, some of which conjugates with free carnitine to produce the increased concentration of an acylcarnitine.

At least 11 organic acid disorders have been identified by expanded newborn screening, most of which are included in [Tables 27-2 and 27-3](#), with the acylcarnitine elevation by which they are detected. The clinical phenotype of the organic acid disorders includes an acute neonatal presentation with metabolic acidosis, hyperammonemia, hepatomegaly and liver dysfunction, perhaps hypoglycemia, and leukopenia or pancytopenia. Such infants are profoundly ill and require emergency measures that include cessation of protein intake and intravenous fluids to provide calories and correct the metabolic imbalance. The most frequent of the organic acid disorders detected by newborn screening that are most likely to have this presentation are propionic acidemia, methylmalonic acidemia, and isovaleric acidemia. Once the infant is stabilized, chronic therapy includes a special diet reduced in the precursor amino acids that lead to the organic acid accumulation and a high caloric intake. These organic acidemias may also have a later onset with a chronic course characterized by developmental delay and other neurologic abnormalities. In addition, many if not most infants with isovaleric acidemia identified by newborn screening have had a mutation that seems to confer a milder or perhaps benign form of the disorder ([65](#)).

Glutaric acidemia type I (GA I) has a more chronic presentation. Affected infants appear to be normal during their first months of life but sometime in the first or second year develop a severe dystonia. Often the onset of dystonia closely follows immunization or an acute febrile illness. Other organic acidemias in [Table 27-3](#) have a variable expression, ranging from a benign course to episodic hypoglycemia with metabolic acidosis and hypotonia, usually not occurring until late infancy or childhood. 3-Methylcrotonyl-CoA carboxylase (3-MCC) deficiency seems to be especially frequent in newborn screening and to often have a benign course ([65](#)). Moreover, in a number of instances in which the infant is screen positive for possible 3-MCC deficiency, the abnormality in the newborn screen proves to be transient and follow-up testing

shows that the mother, not the infant, has the disorder (maternal 3-MCC deficiency).

### 27.5.9 Fatty Acid Oxidation Disorders

Fatty acid oxidation primarily occurs in mitochondria and is critical for energy generation in the fasting state or during exercise. The sequence of fatty acid oxidation includes linkage of the fatty acids to carnitine for transport into the mitochondria, decoupling from carnitine within the mitochondria, and  $\beta$ -oxidation to yield ketones. Each step involves one or more transport or enzyme reactions. Notably, several enzymes, including chain length specific dehydrogenases, are involved in  $\beta$ -oxidation. Chapter 97 in this book describes the pathways of fatty acid oxidation and the FAODs. All the known disorders can be detected by expanded newborn screening ([Tables 27-2 and 27-3](#)). The cardinal feature of FAOD is hypoketotic hypoglycemia. This may present in the neonate and the most likely to do so is MCADD. When MCADD is expressed in the neonate, the hypoglycemia is usually accompanied by metabolic acidosis, hyperammonemia, and hepatomegaly with some degree of liver dysfunction. Neonatal expression has also been described with very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD). The latter is usually associated with hypertrophic cardiomyopathy that can cause an arrhythmia in the neonate but is more frequently not recognized until later in infancy. Long-chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD) and mitochondrial trifunctional protein deficiency usually have a chronic course that includes liver disease and retinopathy. Carnitine transport defect may produce severe cardiomyopathy and general myopathy in the neonate and can be life threatening. The neonatal expression of carnitine palmitoyltransferase II (CPT II) deficiency is associated with multiple congenital defects and is usually lethal. Short-chain acyl-CoA dehydrogenase deficiency (SCADD) has been reported to have a neonatal expression but current evidence indicates that it is most likely a benign disorder ([66,67](#)).

Despite the possibility of a neonatal presentation, the most important reason to include FAOD in neonatal screening is the high risk of sudden death. This may happen in infancy or in the second or third year of life. The factor that leads to sudden death is almost always vomiting and reduced intake, usually due to an acute illness such as gastroenteritis or upper respiratory infection ([68](#)). The vomiting with the accompanying reduced food intake (“fasting”) provokes hypoglycemia. MCADD is the most frequent of the FAODs and certainly the FAOD that is most prone to sudden death. Nevertheless, many if not most infants identified with MCADD seem to have a mild form of the disorder that may be benign. Evidence suggests that the level of C8 in the initial newborn screen might serve to differentiate infants with clinically significant disease from those with perhaps an insignificant form ([68](#)).

The major treatment of an identified FAOD is prompt attention to any illness in which there is repeated vomiting and lack of intake as well as fasting for more than 10–12 h. Treatment requires intravenous glucose (D10) and hospitalization until vomiting ceases and food intake commences. Chronic treatment includes carnitine supplementation to treat or prevent secondary carnitine deficiency. VLCADD and LCHADD treatment also includes medium-chain triglycerides (MCT) to provide the fatty acids distal to the metabolic block and allow ketones to be formed. For carnitine uptake defect, the treatment is carnitine supplementation. Notably, as in 3-MCC deficiency, maternal carnitine uptake disorder characterized by a low free carnitine level in the mother has been identified in a number of families wherein the carnitine deficiency in the neonate has been transient (69).

## 27.6 OTHER NEWBORN SCREENING

Newborn screening programs in varying numbers of states screen for additional inherited and acquired disorders including congenital hypothyroidism, CAH, CF, and hemoglobinopathies.

### 27.6.1 Congenital Adrenal Hyperplasia

Screening for CAH became technically feasible in 1977 when Pang and colleagues (1) introduced an immunoassay using Guthrie specimens to measure 17-OHP in order to detect CAH due to 21-hydroxylase deficiency, which accounts for more than 90% of all cases. Nationwide and regional screening programs for CAH were subsequently introduced in several countries. Worldwide incidence of CAH was estimated at 1:15,000 live births, with the salt-wasting form comprising 75% of the total and often causing hypovolemic shock and death in newborns and the simple-virilizing form, which does not result in spontaneous hypovolemia, comprising 25%. Molecular testing suggests that the proportion of affected newborns that have the salt-wasting form is closer to 60% (19). Initial screening is by immunoassay for 17-OHP; a second screen is performed in some programs. Most programs have established cutoff levels among programs related to prematurity or low birth weight. Follow-up is often by referral to a medical consultant. Neonatal screening aims to prevent deaths from delayed recognition and treatment of the salt-wasting form, to prevent sex misassignment of affected female newborns that can occur with either the salt-wasting or simple-virilizing forms, and possibly to prevent premature epiphyseal closure in children with simple-virilizing CAH (see also Chapter 87, Genetic Disorders of the Adrenal Gland).

### 27.6.2 Cystic Fibrosis

Newborn screening for CF by measuring the IRT in dried blood followed by DNA analysis for varying number of CF mutations has been widely implemented in the

United States and some other countries. Newborns in all 50 US states are now screened for CF. CF was included among the 29 core disorders in the national uniform panel (4) following endorsements of the screening by the US Centers for Disease Control and Prevention (CDC) and the recommendation of the US Cystic Fibrosis Foundation. Several longer term studies from Wisconsin provided evidence of nutritional and developmental benefits, and improved survival in CF newborns (70). Newborns in Australia have been screened for CF for many years. The most convincing evidence of a short-term benefit was the demonstration that the number of hospital days during the first 2 years of life required by children with CF identified by screening 400,000 newborns in Australia was lower for the screened patients than in affected children born prior to screening. Long-term benefits have also been demonstrated in Australia (71).

Based on detailed analysis, the CDC concluded that the net balance of benefits and risks was favorable if state programs were of high quality and carefully monitored (72). Current CF newborn screening in North America and Australia, and in some European countries, begins with the measurement of IRT in the Guthrie specimen. Most US programs use an IRT/DNA algorithm (73). Specimens with IRT values exceeding the cutoff are analyzed for either the common F508del *CFTR* mutant allele alone or, more often, a panel of up to 400 *CFTR* mutations. The mutations used may include *CFTR* alleles from the ACMG 23 mutation panel or others based on the allele frequencies in local populations. Some programs follow up with *CFTR* gene scanning and selective sequencing (74). Based on the magnitude of the IRT elevation, along with the number and identity of the *CFTR* mutations, screen-positive infants are referred for sweat testing, medical management and genetic counseling (see also Chapter 58, Cystic Fibrosis).

### 27.6.3 Hemoglobinopathies and Thalassemias

Most programs in the United States screen newborns for hemoglobinopathies, particularly those involving sickle hemoglobin, with the primary objective of detecting the sickle-cell diseases. The initial screen is most frequently by means of isoelectric focusing, less often by high-performance liquid chromatography or cellulose acetate electrophoresis. Confirmatory testing also uses these methods, and programs are increasingly adding genotyping by DNA analysis for this purpose. The early identification of infants with one of the sickling hemoglobinopathies coupled with aggressive follow-up has been shown to result in a significant reduction of mortality during the early years when the risks are especially great. Moreover, the investigators in the multicenter oral penicillin prophylaxis trial achieved an 84% reduction in the incidence of pneumococcal disease, a major cause of early morbidity and mortality in the sickling disorders, by means of inexpensive and safe treatment with

penicillin. In addition to treatment of affected newborns and genetic counseling of their parents, some programs attempt to follow up the parents of carrier newborns in order to identify and counsel those couples in which both are carriers. Ascertainment of 28 at-risk pregnant women as a result of parent testing in a large newborn hemoglobinopathy screening program led to amniocentesis in 14 and elective termination of three of the four affected pregnancies. In contrast, only a small percentage of those couples ascertained by means of prenatal carrier screening in a large program with pregnancies at risk for a serious globin disorder chose to use prenatal diagnosis (1). Screening programs outside major metropolitan areas have addressed the issue of whether to screen all newborns and have accepted the additional costs and problems that accompany increasing program size rather than attempt to identify and screen only those newborns that, based on racial or other criteria, are considered to be at risk (see also Chapter 71, Hemoglobinopathies and Thalassemias).

### 27.6.4 Congenital Hypothyroidism

Congenital hypothyroidism was once a prominent cause of mental retardation but identification by newborn screening followed by therapy with T4 has virtually eliminated retardation from this disorder. Screening for congenital hypothyroidism began in 1974 with the introduction of a radioimmunoassay for T4 applicable to the newborn filter paper blood specimens (2). Screening for congenital hypothyroidism is now part of many programs and has had the interesting effect of promoting regionalization of screening because the immunoassay used for hypothyroidism was technically more complicated than the bacterial assays used for inborn error screening at that time. Many programs now use elevated TSH as the marker for identifying congenital hypothyroidism. A T4 value two standard deviations or more below the mean or a markedly increased level of TSH or both suggest the presence of congenital hypothyroidism in the infant and the parents and physician are advised to obtain additional testing and possible treatment. This approach identifies congenital hypothyroidism in approximately 1:3600 to 1:5000 newborns (75). Although commonly combined with newborn screening for principally genetic disorders, only a few of the etiologies of congenital hypothyroidism are Mendelian (76) (see also Chapter 84, Thyroid Disorders).

### 27.6.5 Other Disorders

Other disorders that were included in some newborn screening programs but are no longer included are  $\alpha_1$ -antitrypsin deficiency, Duchenne muscular dystrophy, and adenosine deaminase deficiency. The hyperlipidemias have been considered for newborn screening. To date, only severe combined immune deficiency (SCID) has

been recommended for addition to the uniform screening panel. SCID newborn screening has been initiated in a number of states using the circles assay described by Puck (77).

### 27.6.6 Lysosomal Disorders

The potential role for and importance of newborn screening has been heightened by other developments. Specific enzyme therapy for Gaucher disease became available in 1994. Specific enzyme therapies have become available for mucopolysaccharidosis type I (MPS I—Hurler, Hurler–Scheie and Scheie syndromes), mucopolysaccharidosis type II (MPS II—Hunter syndrome), glycogen storage disease type II (Pompe disease), and mucopolysaccharidosis type VI (MPS VI—Maroteaux–Lamy syndrome). Substrate-diverting medications have also been developed for several of these. Experience with enzyme therapies in already diagnosed adults and older children has shown that, in general, the course of the pathologic changes in these disorders can be slowed but not substantially reversed, except perhaps for hepatosplenomegaly. Hematopoietic stem cell transplantation (HSCT), involving the intravenous infusion of autologous or allogeneic stem cells collected from bone marrow, peripheral blood, or umbilical cord blood, has also been used successfully in several of these disorders. In most cases, HSCT must be done in the earliest stages of the disease to be successful. Detection at the earliest possible time has thus seemed to offer the greatest opportunity for successful treatment.

In response to strong and organized advocacy, in August 2006, New York became the first state in the United States to initiate population-wide screening for a lysosomal disorder. Scientists at the Wadsworth Center in Albany (78) successfully adapted previous high-throughput methods (79,80) for the measurement of galactocerebrosidase (GALC) by MS/MS in blood spots. The initial analysis of the galactocerebrosidase activity of 139,074 anonymous newborns, 56 known carriers, and 16 Krabbe patients using a MS/MS method provided data to establish cutoffs and a diagnostic algorithm. Blood specimens with reproducibly low GALC activity were analyzed for GALC mutations, particularly for homozygosity for the 30-kb deletion because of its strong association with early infantile Krabbe disease. Directed primarily toward the early ascertainment of the severe infantile form of Krabbe disease for the purpose of prompt stem cell transplantation, the complexities in this disorder posed obstacles. Initial discussions involving the directors of the regional Metabolic Disease Treatment Centers to whom screen-positive newborns would be referred for confirmation and management raised concerns about many unresolved issues. Uncertainties were apparent regarding the methods for establishing the diagnosis of the infantile form as well as for

ruling it out. Facilities with the expertise needed for confirmatory laboratory and clinical testing, and for HSCT, were limited. The discussions were broadened with the formation of the Krabbe Disease Consortium, the composition and initial deliberations of which have been described (81). The participants included the directors of the eight metabolic disease specialty centers of New York and scientists from the New York State (NYS) screening laboratory along with child neurologists at all the participating institutions, neuroradiologists, neurophysiologists, transplant physicians, neurodevelopmental pediatricians, among others. The Consortium developed an algorithm for classifying screen-positive newborns into high-, moderate- and low-risk categories, each associated with a specific plan for diagnostic and clinical follow-up. Positive screens proved to be more frequent than was initially expected from the estimated population frequency for infantile Krabbe disease of 1 in 100,000 births. Screening of more than 1.45 million newborns since its inception five and one-half years ago has led to referral of 248 infants for neurodiagnostic evaluation in the regional centers. Follow-up laboratory measurements and neurodiagnostic studies have for many of these infants indicated no further concerns or placed them in the low-risk category. Experience during the past few years has shown that a substantial number of newborns who had GALC activities in the moderate- or high-risk range did not develop the infantile-onset phenotype, although concerns remain about the possible development of later onset forms of Krabbe disease. Four newborns were originally identified as affected. One family declined transplant and the child is currently in a palliative care facility. Three have been transplanted. One died in transplant of multiorgan failure. Another developed chronic autoimmune hemolytic anemia and the steroid treatment has led to cardiomyopathy and steroid myopathy. The third was already symptomatic when transplanted at three weeks of age and reportedly has severe neurologic impairments. None of the remaining high-risk newborns and none of the moderate- or low-risk children has developed clinical signs of disease. The Krabbe Disease Consortium has continued to meet to discuss further developments and the many remaining issues and uncertainties. Pending legislation in New York would require screening of newborns for Fabry, Gaucher, Pompe and Niemann–Pick types A and B diseases. Similar bills have been passed in Illinois, Missouri and New Mexico.

Addition of Krabbe disease screening has been proposed under the established formal process for individuals or organizations to nominate a heritable disorder to be considered for inclusion in the recommended uniform screening panel. As indicated on the Web site of the Advisory Committee on Heritable Disorders in Newborns and Children [Web resource 5], six conditions have been proposed to the Advisory Committee: Krabbe disease, Fabry disease, Niemann–Pick disease, Pompe disease, SCID,

and (SMA). The considerations underlying the decision not to approve at this time the requests for the addition of Krabbe disease corresponded to many of the concerns expressed by the Krabbe Disease Consortium (82).

## 27.7 ISSUES AND CONCERNS IN SCREENING

Most screening tests are designed to be sufficiently sensitive to minimize false-negative results, but this reduces specificity and renders them seldom diagnostic. Accurate and definitive diagnosis requires additional testing in nearly all instances. Regardless of sensitivity, false-negative results occur with every screening procedure, so a negative result from screening should not preclude appropriate evaluation for a disorder suspected clinically.

Most newborn screening programs store the newborn screening specimen after the testing has been completed. The original purpose was to have the specimen available for retesting should the child be clinically identified with a disorder but have had a presumably normal newborn screening result. This might identify flaws in the screening process, either an incorrect cutoff level or a laboratory error, or show that the newborn screening marker for a disorder is not always present in an affected baby. In fact, the stored specimen has been a very valuable source of information for all three of these purposes. The metabolites have been found to be surprisingly stable in the stored specimen, especially under optimal storage conditions (78). The duration of storage varies widely among programs, ranging from a few weeks to decades. Because it is possible to perform extensive DNA analysis in the specimen, the policy of storage has been included in the category of “biobanking,” provoking controversy and, in some instances, a legal challenge to the practice. Procedures are being developed to require consent for the use of the stored specimen and to ensure strict confidentiality of testing results (84).

Expanded newborn screening by MS/MS has resulted in substantially higher frequencies of certain disorders than expected on the basis of previous clinical ascertainment. While there is no doubt that expanded screening has substantially improved the short-term outcome of many metabolic disorders (85,86), the greater number of cases has led to uncertainty of clinical significance in many of the identified infants (87,88). This uncertainty as well as the need to assess long-term outcome in all disorders has led to plans for the development of a national long-term follow-up study within the structure of the Newborn Screening Translational Research Network organized by the ACMG (89). Within regional screening programs, several long-term follow-up efforts are underway (90–94).

Screening programs and procedures should meet a variety of criteria both before they are implemented and continually during their operation. These criteria include technical, educational, and organizational aspects. A high signal-to-noise ratio is needed to maximize effectiveness

and minimize adverse effects. The noise in the system includes the true biological variation of the character being measured in the screened population and the variation within the testing procedure itself. In addition to normal biological variation and transient abnormalities, confusing artifacts are produced by contamination of blood and urine specimens with microorganisms, drugs used systemically or locally, diaper powder, food supplements, and the like. Disentangling these sources of confusion and delay requires great expertise. As noted earlier, positive results in a screening test necessitate repeat testing with follow-up and additional testing, possibly over a period of weeks or months. These can be expensive in terms of personnel, materials, and parental anxiety and inconvenience (6). The rarer the trait being sought by screening, the higher will be the proportion of false positives.

Finally, screening programs should be organized and administered in such a way that they are constantly updated to incorporate the latest technical and medical advances. They must also be responsive to changes in society. After several decades with few fundamental changes in neonatal screening programs, the recent discussions centered on the potential advantages and limitations of expanded screening based on MS/MS technology has stimulated much debate and discussion. Advocacy groups consisting of professionals, parents of affected children, and others have increasingly appealed to screening programs themselves and to state legislatures for the addition of this screening that detects a number of disorders not detected by other screening methods. Interest has focused particularly on disorders such as GA I and MCADD. In both disorders, early presymptomatic therapy and anticipation of acute intercurrent illness can prevent the otherwise irreversible brain damage or sudden death. Moreover, the interval between birth and the first episode is sufficiently long to allow an appropriate metabolic diagnosis. These considerations would seem to strongly favor inclusion of these disorders in routine newborn screening.

The introduction of MS/MS technologies in several of the larger screening programs has stimulated a major reevaluation of newborn metabolic screening after many years of relative constancy (95). The widespread inclusion of this or other new technologies in screening programs requires that the traditional questions and issues be addressed. Is the frequency of the disorder detected sufficiently great to justify screening? Are the genetic heterogeneity, expression, and natural history of the disorder well characterized? Is an effective treatment available and, if so, must it begin shortly after birth or will it be equally effective if started later? What is the detection rate, and what are the frequencies of false-positive and false-negative screening test results? Is the screen cost-effective? Discussions and debates regarding the claims, issues, and concerns about disorders and conditions to be screened will likely produce major and extensive changes in screening programs over the next few years.

## GLOSSARY

**Algorithm** – a scheme for sequential testing to confirm or reject the diagnosis of a disorder.

**Amino acid disorder** – a metabolic abnormality in the catabolism of an amino acid resulting in an increase in the amino acid and clinical problems that often include mental retardation.

**Bacterial (inhibition) assay** – a test on a bacterial plate that responds to an increased level of an amino acid by growth around a disc from the Guthrie newborn screening specimen.

**Conditions, core and secondary** – core conditions are those disorders that the American College of Medical Genetics recommended as primary targets for newborn screening in all states. Secondary conditions are those disorders identified in newborn screening as a result of screening for the core conditions.

**DNA-based gene tests** – in newborn screening this refers to tests of genes in the DNA of the dried blood specimen for the purpose of either primary newborn screening (e.g. screening for SCID) or as second-tier screening of the newborn specimen in which an abnormality was identified in the initial newborn screen (e.g. cystic fibrosis).

**Exome and genome sequencing** – exome sequencing is a strategy to selectively sequence the coding regions of the genome to identify novel genes associated with rare and common disorders. Whole genome sequencing refers to sequencing all of the bases in the genome of an individual.

**Expanded newborn screening** – expansion of newborn screening using MS/MS to include many metabolic disorders not previously identifiable by newborn screening.

**False-positive result** – concluding that after additional testing an individual initially identified in screening as possibly having a disorder does not have the disorder.

**Fatty acid oxidation defect** – a metabolic abnormality in the mitochondrial oxidation of fatty acids resulting in the lack of ketone production, especially harmful when glucose is limiting and ketones are required as a source of energy.

**Genotype–phenotype correlation** – the degree to which a genotype predicts the clinical severity of a genetic disorder.

**Guthrie specimen or card** – the dried blood on filter paper collected from the heel of the infant and sent for newborn screening to a newborn screening laboratory.

**Lysosomal storage disease** – any one of a large number of disorders caused by a defect in one of the lysosomal enzymes, resulting in the accumulation of the molecular substrate for that enzymes. The accumulation is usually in neurons and/or reticuloendothelial cells.

**Organic academia** – a metabolic abnormality in the catabolism of an organic acid resulting in an increase in the organic acid as well as related organic acid metabolites, which produce metabolic acidosis as well as secondary clinical problems.

**Phenylalanine-restricted diet** – a special diet markedly reduced in phenylalanine for the treatment of PKU. It is composed of foods very low in protein (e.g. fruits and vegetables) and an elemental formula consisting of required amino acids except for phenylalanine with added vitamins, minerals, a carbohydrate source and, often, fat.

**Positive predictive value (PPV)** – the likelihood that an individual has the disorder for which the screening is conducted after identification in population screening.

**Screening test and diagnostic test** – a screening test is a test applied to a population (i.e. all newborns) to identify the rare individual in that population who has an abnormality on that test while eliminating from consideration almost all (but not all) other members of that population. The test should have high sensitivity but low specificity. A diagnostic test is a test with both high sensitivity and high specificity that distinguishes the individual identified by newborn screening who has the disorder from those who screened positive but are not affected.

**Second-tier testing** – additional testing of the Guthrie newborn screening specimen by a technique not used in routine newborn screening to increase specificity for a disorder identified by initial newborn screening.

**Sickle-cell disease** – an inherited hematological disorder in which the hemoglobin is abnormal and tends to form the shape of a sickle, especially under conditions of low oxygen. Includes sickle-cell anemia (hemoglobin SS), SC disease (hemoglobin SC) and beta-thalassemia (hemoglobin S<sup>thal</sup>).

**Tandem mass spectrometry (MS/MS)** – a test method that measures amino acids and carnitine-linked organic and fatty acids used in newborn screening as well as to confirm metabolic disorders identified in newborn screening.

**Urea cycle disorder** – a metabolic abnormality in the urea cycle resulting in hyperammonemia and reduced urea synthesis.

### Biographies

**Richard W Erbe** received his MD degree in 1964 from the University of Michigan Medical School in Ann Arbor. He completed Residency in Medicine at the Peter Bent Brigham Hospital and Harvard Medical School in Boston. Thereafter, he was a research associate with Dr Philip Leder at the National Cancer Institute, then research fellow in the Department of Biological Chemistry at Harvard Medical School. In 1970, he joined Dr John W. Littlefield in the Genetics Unit at the Massachusetts General Hospital, later becoming Chief as well as associate professor of Pediatrics and Genetics at Harvard Medical School. During this time he was Director of the NIGMS Genetics Training Grant and Program (postdoctoral) at Harvard Medical School; Founding Codirector with Dr Allen Crocker of the New England Genetics Group; Chair of the American Society of Human Genetics Program Committee (1979–1982); and Member, Editorial Board, New England Journal of Medicine (1976–1979). He is certified by the American Board of Internal Medicine (1974) and the American Board of Medical Genetics (Clinical Genetics 1982, Clinical Cytogenetics 1993, and Clinical Molecular Genetics 1993). In 1989, he moved to the Children's Hospital of Buffalo and SUNY Buffalo, where he is Chief of the Division of Genetics and Director of the Metabolism Program. His research interests focus on inborn errors of folate metabolism, and biochemical and molecular genetics.

**Harvey L Levy, MD**, is senior physician in Medicine and Genetics at Children's Hospital Boston and professor of Pediatrics at Harvard Medical School. He has been involved in metabolic disorders for over 40 years. This involvement includes newborn screening, diagnosing and treating children and adults, and research. Dr Levy attended Emory University in Atlanta and obtained his medical degree from the Medical College of Georgia. He trained in pediatrics in Boston, New York, and Baltimore, then concentrated in metabolic disorders under one of the pioneers, Dr Mary Efron, at the Massachusetts General Hospital. Following this training he served on the faculty at the Massachusetts General Hospital, Director of the Massachusetts Metabolic Disorders Program, and Chief of Biochemical Genetics in the New England Newborn Screening Program. For the past 33 years he has been at the Children's Hospital, Boston, and has served as director of the Metabolic Program, Director of Metabolic Research and the Maternal PKU Program and, currently, attending in metabolism. He has authored over 400 publications on metabolic disorders, including journal articles, books, chapters and reviews. A major interest has been the process and follow-up of newborn screening, particularly the study of outcome in metabolic disorders identified by screening.

### 28.1 INTRODUCTION

There has been remarkable progress in the ability to treat lysosomal storage diseases. Enzyme replacement therapy (ERT), bone marrow transplantation, and substrate deprivation are currently being used to treat these disorders, and the potential of pharmacologic chaperones, gene augmentation, and stem cell therapies is being investigated (1–7). This review focuses on the current status and the lessons learned from treatment of lysosomal storage diseases by ERT and describes the potential of emerging therapeutic strategies for the treatment of the visceral as well as the central nervous system (CNS) manifestations of these diseases.

About 40 years ago, Nobel Laureate Christian de Duve first suggested that lysosomal diseases could be treated by replacing the defective enzyme with its normal counterpart (8). Subsequent experiments demonstrated that when the appropriate active normal enzyme was added to the media of enzyme-deficient cultured fibroblasts from individuals with various lysosomal storage diseases, the exogenous enzyme gained access to and degraded the substrates accumulated in the lysosomes (9–11). Of note, only 1–5% of normal intracellular enzyme activity was required to correct the metabolic defects in the enzyme-deficient cells. The subsequent discovery that lysosomal enzyme glycoproteins are targeted to the lysosome by the mannose 6-phosphate residues on their oligosaccharide chains provided further rationale for the treatment of lysosomal disorders by ERT (12,13). The pathway mediated by mannose 6-phosphate receptor is

responsible for the intracellular delivery of newly synthesized lysosomal enzymes to the lysosomes, as well as for the delivery of exogenously supplied normal lysosomal enzymes to the lysosomes via the mannose 6-phosphate receptors on the plasma membranes of most cell types (for reviews, see Kornfeld (12) and Sabatini and Adesnik (13)). These studies indicated the feasibility of ERT and, in particular, that exogenous lysosomal enzymes could gain access to intracellular lysosomal sites and that low levels of enzyme activity could metabolize the accumulated substrate(s) in cellular lysosomes. Thus, these findings provided the rationale for the early clinical studies of ERT in lysosomal storage diseases. However, it was not until the early 1990s that ERT became a reality with the demonstration of its safety and effectiveness in patients with type 1 Gaucher disease (14,15). Subsequently, ERT was approved for Fabry disease, Pompe disease and mucopolysaccharidoses I, II and VI, and clinical testing of ERT for Niemann–Pick disease (NPD) type B and mucopolysaccharidosis IVA are in progress. Table 28-1 lists the lysosomal storage diseases treatable by ERT.

The fact that ERT does not correct all the manifestations of lysosomal storage diseases or does not effectively address neuropathic diseases has prompted investigations into the potential use of small molecule drugs (for recent review, see Smid (16)). These alternate therapies could be deployed either as stand-alone or adjuvant therapies to ERT. One of the more developed concepts is referred to as substrate reduction therapy (SRT), which seeks to reduce the rate of biosynthesis of the substrate (17–20).

TABLE 28-1    Lysosomal Diseases Treatable by ERT						
Disease/Subtypes	Deficient Enzyme	Inheritance	Residual Activity	CNS Involvement	Primary Site of Pathology	Major Manifestations
<b>Gaucher disease type 1</b>	Acid $\beta$ -glucocerebrosidase	AR	+	–	RES	Hepatosplenomegaly, skeletal disease
<b>Fabry disease</b>						
Classic	$\alpha$ -Galactosidase A	XLR	–	–	Vascular endothelium	Renal failure, pain, skin lesions, stroke
Later-onset cardiac variant	$\alpha$ -Galactosidase A	XLR	+	–	Cardiomyocytes	Cardiomegaly, arrhythmias & failure
<b>Pompe disease</b>						
Infantile	$\alpha$ -Glucosidase	AR	–	–	Cardiomyocytes	Cardiomegaly, muscular weakness
Later-onset type	$\alpha$ -Glucosidase	AR	+	–	Myocytes	Muscular weakness
<b>MPS I</b>						
Hurler	$\alpha$ -L-Iduronidase	AR	–	+	CTC, RES, neurons	Skeletal disease, organomegaly, hearing loss
Hurler–Scheie	$\alpha$ -L-Iduronidase	AR	+	–	CTC, RES	Intermediate phenotype between Hurler and Scheie
Scheie	$\alpha$ -L-Iduronidase	AR	+	–	CTC	Corneal clouding, joint contractures, normal intelligence
<b>MPS II</b>						
Severe	Iduronate sulfatase	XLR	–	+	CTC, RES	Skeletal disease, neurons organomegaly, early demise
Mild	Iduronate sulfatase	XLR	+	–	CTC, RES	Normal intelligence, short stature, normal life span
<b>MPS VI</b>	Arylsulfatase B	AR	–	+	RES, CTC	Corneal clouding, normal intelligence
<b>MPS VII</b>						
Infantile	$\beta$ -Glucuronidase	AR	–	–	CTC, RES neurons	Skeletal disease, hepatosplenomegaly, normal intelligence
Adult	$\beta$ -Glucuronidase	AR	+	–	CTC, RES	Skeletal disease, hepatosplenomegaly, normal intelligence
<b>Nieman–Pick disease type B</b>	Acid sphingomyelinase	AR	+	–	RES	Hepatosplenomegaly, pulmonary insufficiency, normal intelligence
<b>Wolman disease</b>	Acid lipase	AR	–	–	Liver	Hepatosplenomegaly, steatorrhea, death before 1 year of life
<b>Cholesteryl ester storage disease</b>	Acid lipase	AR	+	–		Hepatosplenomegaly, widespread lipid storage

AR, autosomal recessive; CTC, connective tissue cells; RES, reticuloendothelial system; XLR, X-linked recessive.

The intent is to reduce the burden of accumulation of the offending substrates, thereby offsetting the catabolic deficiency and restoring the balance between the rate of biosynthesis and catabolism. At present, an inhibitor of glucosylceramide synthase (miglustat), the enzyme that catalyzes the first step in the synthesis of glycosphingolipids, is approved for treating patients with mild type I Gaucher disease (21). As miglustat is reportedly able to traverse the blood–brain barrier, it has also been approved in Europe for treating NPD type C (22).

The use of small molecules that act as pharmacologic chaperones to rescue misfolded/mistrafficked mutant proteins provides a novel and attractive approach for the treatment of protein misfolding disorders (for recent reviews, see Perlmutter (23), Cohen and Kelly (8), Desnick (24), and Ulloa-Aguirre and colleagues (25)). For lysosomal enzymopathies, this therapeutic strategy involves the use of reversible competitive enzyme inhibitors that can rescue misfolded/mistrafficked enzymes that would otherwise be transported to the proteasome for degradation by the endoplasmic reticulum-associated degradation (ERAD) machinery (for reviews, see Hampton (26), Ulloa-Aguirre and colleagues (25), and Meusser and coworkers (27)). Pharmacologic chaperones are attractive therapeutic agents as they can be orally administered, may cross the blood–brain barrier, and presumably can gain access to most or all cell types. These small molecule chaperones have entered clinical testing for Fabry, Pompe, and Gaucher diseases.

An emerging technology platform for treating lysosomal storage disorders is gene augmentation therapy (for review, see Chapter 29). This approach seeks to genetically modify a subset of patients' cells *in situ* to produce and secrete the deficient enzymes into systemic circulation. As the enzymes are expressed continuously, the higher bioavailability might facilitate improved efficacy, particularly for those organs that are not well served by periodic infusions of exogenous enzymes. This modification can be realized using a number of gene transfer systems of viral and nonviral origin (for reviews, see Cheng (28), Biffi (29), Sands (30)). The most advanced of these delivery systems is that based on adeno-associated viral (AAV) vectors. While systemic gene therapy with recombinant AAV vectors for lysosomal storage diseases is still in preclinical research, this technology is in clinical development for other genetic diseases. Similar vector systems have also been employed to deliver the therapy directly to the CNS to address lysosomal storage diseases with neuropathic disease. Although the procedure of intracerebral delivery is invasive, reports that expression of the enzymes can persist for a very protracted period provides continued optimism.

In this chapter we review the current status of ERT for lysosomal storage diseases and emphasize the principles for effective treatment. We also provide an overview of emerging therapies for lysosomal diseases and describe recent *in vitro* and *in vivo* studies that highlight the potential of these therapeutic strategies.

## 28.2 ERT FOR LYSOSOMAL STORAGE DISEASES

### 28.2.1 Early Clinical Studies

Beginning in the early 1970s, pilot clinical studies of ERT were undertaken in several lysosomal disorders (Fabry, Gaucher, Pompe, and Sandhoff diseases) by intravenous infusion of the respective normal human enzyme. In each case, the partially purified human enzyme was rapidly cleared from the circulation ( $t_{1/2}$  approximately 10–20 min), and there was evidence for clearance of the respective accumulated substrate(s) (for reviews, see Desnick and coworkers (31,32), Tager and colleagues (33), and Desnick (34)).

These early and encouraging studies supported the feasibility of enzyme replacement with highly purified human enzymes. However, they clearly indicated that the treatment of disorders with primary neuronal involvement was not feasible by this approach, since intravenously administered enzymes did not cross the blood–brain barrier (35). Thus, investigators realized that ERT for disorders with severe neurologic involvement, such as Tay–Sachs disease, Sandhoff disease, and type A NPD, was not feasible and focused their efforts on disorders without significant neurologic involvement.

In 1972, and again in 1979, the March of Dimes Birth Defects Foundation sponsored international workshops on “Enzyme Therapy in Genetic Diseases,” in which basic and clinical scientists reviewed the developments in the area (31,34). In addition, these workshops identified the major obstacles confronting successful ERT in lysosomal diseases, which included (1) the inability to produce and purify sufficient quantities of lysosomal enzymes, including specific glycoforms; (2) the inability to target exogenously administered enzymes to specific tissues and cellular sites of pathology, particularly to the CNS; and (3) the lack of animal models of human lysosomal diseases to evaluate the pharmacokinetic and pharmacodynamic effects of enzyme administration.

### 28.2.2 ERT Proven Safe and Effective in Type 1 Gaucher Disease

In the 1980s, many researchers found the obstacles to ERT too formidable to pursue and focused their research on more basic studies of lysosomal biology and disease. Only a few researchers continued to pursue clinical studies of ERT. Among these, Dr Roscoe Brady and colleagues at the National Institutes of Health were determined to develop ERT for type 1 Gaucher disease, which is caused by the deficient activity of  $\beta$ -glucocerebrosidase (36). The primary cellular site of pathology in Gaucher disease is the macrophage/monocyte system, and the bone marrow and reticuloendothelial organs of affected individuals become infiltrated with lipid-laden “foam” cells, known as “Gaucher” cells. Patients develop massive enlargement of their

livers and spleens, pancytopenia, and severe skeletal disease causing severe bone pain and pathologic fractures.

Brady's group sought to reverse, or at least halt, the disease progression by ERT with  $\beta$ -glucocerebrosidase purified from human placenta. Although most lysosomal glycoproteins are targeted to the lysosome via the trafficking system mediated by mannose 6-phosphate receptor,  $\beta$ -glucocerebrosidase was not. It was shown that  $\beta$ -glucocerebrosidase was targeted to the mannose-specific receptors on macrophages, the primary cellular site of pathology in type 1 Gaucher disease. This was accomplished by modifying the enzyme's *N*-linked oligosaccharide chains by sequentially removing the sialic acid,  $\beta$ -galactosyl, and  $\beta$ -*N*-acetylglucosaminyl residues, thus exposing the mannose residues (37). This "mannose-terminated" form of the enzyme was efficiently recognized by the abundant mannose receptors on macrophage membranes and then delivered to macrophage lysosomes for substrate catabolism (37). Early results of enzyme replacement using the mannose-terminated enzyme had encouraging but limited clinical effects, presumably because of the small doses administered (38).

Many investigators were skeptical about the prospects for enzyme therapy until Brady's group reported in the early 1990s that weekly or biweekly intravenous infusions of large doses (2–3 mg/kg) of the mannose-terminated enzyme markedly reduced the hepatosplenomegaly, improved the hematologic values, and led to substantial improvements in bone density and other clinical manifestations in these patients (14,15,39). Their demonstration that biweekly ERT was safe and well tolerated, and that the enzyme could reverse years of substrate accumulation in these patients, provided the first clinical "proof of principle" for ERT in lysosomal disorders without primary neurologic involvement.

Initially,  $\beta$ -glucocerebrosidase was purified from human placenta by industrial-scale techniques; later, the recombinant human enzyme produced in Chinese hamster ovary (CHO) cells was shown to be equally effective (40). Since a viable murine or naturally occurring animal model for Gaucher disease did not exist, investigators experimented with the dose and dose schedule to determine the minimum effective dose of the enzyme in order to decrease the cost of therapy. Eventually, it was appreciated that clinical response was dose dependent and that the maintenance dose was not significantly different from the dose originally used to reverse years of substrate accumulation. During the past 15 years, worldwide experience with ERT in over 4000 patients with type 1 Gaucher disease has clearly documented its safety and effectiveness (for reviews, see Grabowski and associates (41) and Weinreb and colleagues (42)).

Table 28-2 lists the principles learned from over a decade of treating type 1 Gaucher disease by ERT. Of note, the reversal of lysosomal storage by ERT was unexpected, as most investigators presumed that the storage was irreversible and that, at best, stabilization of the disease process would be obtainable. The principles learned

**TABLE 28-2 Principles of ERT Learned from Gaucher Disease**

<ul style="list-style-type: none"> <li>• Proof of concept: ERT works</li> <li>• Safe and generally well tolerated               <ul style="list-style-type: none"> <li>– Minimal immunologic complications (cross-reactive immunologic material positive (CRIM+) patients)</li> </ul> </li> <li>• Dose-dependent enzyme delivery               <ul style="list-style-type: none"> <li>– Mannose receptor-mediated enzyme uptake</li> <li>– Inability to cross blood–brain barrier</li> </ul> </li> <li>• Dose-dependent substrate clearance</li> <li>• Unexpected reversal of lysosomal storage in organs</li> <li>• Rapid reaccumulation off therapy: lifetime therapy</li> <li>• Need to treat early to prevent irreversible disease</li> </ul>
---

included (1) enzyme delivery was receptor mediated and dose dependent, (2) substrate clearance was dose dependent, (3) decreased dose or cessation of ERT resulted in rapid substrate reaccumulation, and (4) patients experienced clinical benefit. In addition, it soon became apparent that the earlier the ERT was initiated, the more effective it was—even preventive, since irreversible damage (e.g. bone disease, fibrosis) could not be altered.

Over the past few years, alternate sources of recombinant  $\beta$ -glucocerebrosidase have been proposed for use in treating type I Gaucher patients. These so-called biosimilars are made in human fibroblasts (43) through gene activation and transgenic carrot root cells (44). Although all versions contain minor differences in amino acid sequences, comparison of the forms made in CHO cells and human fibroblasts showed no major differences with respect to pharmacokinetics and efficacy in pre-clinical and clinical studies (45,46). It is anticipated that longer term studies in the clinic will be required to fully understand the safety profile of the biosimilars, particularly those that are derived from plant cells.

### 28.2.3 ERT for Other Lysosomal Diseases

The success of ERT in type 1 Gaucher disease stimulated investigators to develop and evaluate enzyme replacement for other lysosomal storage diseases, and the past and current clinical trials of ERT in these diseases are listed in Table 28-3. As discussed in this section, these efforts were facilitated by the cloning of the complementary DNAs (cDNAs) and genes encoding most of the human lysosomal enzymes, the development of eukaryotic expression systems to produce large quantities of recombinant enzyme (i.e. Ioannou and colleagues (47)), and the use of gene-targeting techniques to generate "knockout" murine models for preclinical studies. These advances abrogated two of the major obstacles to ERT: the lack of sufficient amounts of human enzyme and the need for animal models for preclinical studies.

**28.2.3.1 Production of Recombinant Human Enzymes.** Researchers turned to CHO cells to manufacture these enzymes since these cells were easy to grow and

<b>Disease</b>	<b>Human Enzyme Replaced/Source<sup>a</sup></b>	<b>Trial<sup>b</sup></b>	<b>Sponsor<sup>c</sup></b>	<b>No. of Patients</b>	<b>Monthly Dose (mg/kg)</b>	<b>Status</b>

performed posttranslational modifications nearly identical to those of human cells. Importantly, it was discovered that the overexpression of a lysosomal cDNA in CHO cells resulted in the delivery of its glycosylated enzyme to the lysosomes, and, more importantly, that the majority of the recombinant human enzyme was selectively secreted into the culture media (47), thereby facilitating large-scale production of the critical highly glycosylated human enzyme. Of note, the secreted enzymes retained their terminal mannose 6-phosphate and sialic acid residues, whereas the enzyme's oligosaccharide chains were trimmed by glycosidases in the lysosome. Other expression systems using human fibroblasts, transgenic animals, and even plant systems have been used to produce therapeutic enzymes.

**28.2.3.2 Generation of Mouse Models for Lysosomal Storage Diseases and Preclinical Studies of ERT.** The development of gene-targeting technology in the 1990s led investigators to generate mouse models for lysosomal storage diseases, most of which had the biochemical, pathologic, and/or clinical manifestations of their human counterparts. Thus, by the mid-1990s, lysosomal disease researchers had available large quantities of recombinant enzymes and disease-specific animal models to vigorously pursue the development of ERT. Preclinical studies in animal models permitted evaluation of the pharmacokinetics and pharmacodynamics of ERT for lysosomal storage diseases. Since the Gaucher disease knockout mouse was not viable, the first preclinical studies of ERT to demonstrate proof of concept were conducted in Fabry knockout mice in the mid-1990s and reported later (48) (see below).

**28.2.3.3 Factors Affecting Selection of Candidate Lysosomal Disorders for ERT.** Several factors influence the selection of candidate lysosomal disorders for ERT. These include the target site(s) of pathology, the likelihood of reversing certain manifestations (e.g. skeletal, connective tissue, and neural diseases), and the presence or absence of residual enzymatic activity. For example, in type 1 Gaucher disease, the major pathologic cell type is the easily targeted macrophage; however, treatment must begin early to prevent the progressive bone disease as severe bone complications appear to be irreversible. In addition, ERT did not reverse the severe neurologic manifestations in patients with types 2 and 3 Gaucher disease. These results further support the initial findings that infused enzymes could not cross the blood-brain barrier (35) and that CNS manifestations were not treatable by ERT. In Fabry disease, the major site of pathology is the vascular endothelium, which is readily accessed by exogenous enzyme, whereas the dramatic bone and joint abnormalities in mucopolysaccharidoses are due to substrate accumulation in connective tissue matrix and cells (e.g. chondrocytes), which take up little, if any, exogenous enzyme. Thus, the effectiveness of ERT in lysosomal disorders depends on the delivery of sufficient amounts of the infused enzyme to the target sites of pathology and the reversibility of certain clinical manifestations.

Animal model studies have also revealed organ-specific variations in response to ERT, which are primarily due to the biodistribution of the infused enzyme. For example, in Fabry and NPD mice, the tissue distribution of intravenously infused enzyme and the amount and duration of substrate clearance (i.e. pharmacodynamics) from target sites of pathology were clearly dose dependent (48,49). Thus, for each disease, the infused enzymes must be administered in high-enough doses to be delivered to specific and unique cell types.

In addition, therapeutic responsiveness is related to disease subtype and disease-specific mutations. For most lysosomal disorders, patients who inherit mutations that render the gene product absent or nonfunctional manifest the severest form of the disease, often causing a rapid neurodegenerative course (for review, see Chapter 7). Alternatively, mutations that alter the protein's stability or kinetics, but retain residual function, have a milder phenotype. Thus, certain disease subtypes may be more amenable to ERT (or SRT and pharmacologic chaperone therapy (PCT); see later). For example, the mucopolysaccharidosis (MPS) I H subtype (Hurler disease) results in early onset of disease manifestations, including mental retardation, whereas types 1 H/S and I S (Hurler–Scheie and Scheie subtypes, respectively) are characterized by later onset and less-severe disease manifestations, including the absence of mental retardation.

The presence or absence of residual enzymatic activity, even if less than 1% of normal, primarily determines the immunologic response to ERT. In type 1 Gaucher disease, all patients have residual  $\beta$ -glucocerebrosidase activity, and experience with over 4000 type 1 patients has documented that less than 15% raise nonneutralizing immunoglobulin G (IgG) antibodies against the normal enzyme (40,50,51). These antibodies have no effect on efficacy and rarely cause infusion-associated reactions (52). In contrast, up to 90% of patients with classical Fabry disease, who have no or very little residual  $\alpha$ -galactosidase A activity, develop nonneutralizing IgG antibodies after four to six infusions (3,53). Up to half of these patients may experience infusion-associated reactions, including chills, rigors, and/or fevers, which do not affect efficacy and can be managed conservatively by premedication with nonsedating antihistamines and antipyretics and by slowing the infusion rate, since these reactions are directly related to protein load. Importantly, patients who seroconvert decrease their antibody titers with time and may eventually become tolerant. Of note, even in patients with no residual enzyme, the intravenous infusion of the recombinant normal enzyme has been well tolerated and has not precluded treatment.

Clinical trials of ERT using recombinant human enzymes have led to approval of this treatment for patients with Fabry disease (3,30), MPS I (54,55), MPS VI (56), Pompe disease (57–59), and MPS II (60,61) (Table 28-4). These clinical trials are discussed in greater detail later. In addition, clinical trials have begun in NPD

type B. Preclinical studies in knockout mice or naturally occurring animal analogs are underway for several other disorders, including galactosialidosis (62), Wolman disease/cholesteryl ester storage disease (63), and MPS VII (64,65). Most recently, studies in the MPS VII mouse model have documented uptake of recombinant enzyme into the brain when intravenously administered at doses greater than 4 mg/kg/week (66). These findings suggest that high-dose delivery of lysosomal enzymes may result in neural uptake and possible benefit for patients with neurologic involvement. For reviews of ERT and clinical trials, see Desnick and Schuchman (1) and Desnick (24).

**28.2.3.4 Fabry Disease.** Fabry disease is an X-linked recessive disorder resulting from the deficient activity of  $\alpha$ -galactosidase A ( $\alpha$ -Gal A) and the progressive accumulation of primarily globotriaosylceramide (GL-3) in the plasma and in tissue lysosomes throughout the body. In classically affected males, who have no detectable  $\alpha$ -Gal A activity, GL-3 accumulation in the vascular endothelium causes the major disease manifestations (67). Clinical onset in childhood is characterized by severe acroparesthesias, angiokeratoma, hypohidrosis, and corneal/lenticular opacities. With advancing age, the progressive lysosomal GL-3 accumulation, particularly in the microvasculature, leads to renal failure, vascular disease of the heart and brain, and premature demise, typically in the fourth or fifth decade of life. Atypical variants, who have residual  $\alpha$ -Gal A activity and no vascular endothelial involvement, have later-onset manifestations, usually limited to the heart or kidneys (i.e. the “cardiac variants”).

The studies of ERT for Fabry disease included the first preclinical studies of various recombinant enzyme glycoforms in the Fabry mouse, which determined the pharmacokinetics and pharmacodynamics for ERT in lysosomal diseases; a Phase 1/2 clinical trial that evaluated dose and dose schedule; a large multicenter, multinational, randomized double-blind placebo-controlled

Phase 3 clinical trial that demonstrated clearance of the accumulated GL-3; and a Phase 4 clinical trial that demonstrated clinical benefit, even in patients with advanced disease.

**28.2.3.4.1 Early Clinical Trials.** Early pilot trials of enzyme replacement in Fabry disease indicated the feasibility of this therapeutic approach as early as 1970 (68–70). However, the rate-limiting obstacles were the inability to produce sufficient amounts of purified normal enzyme and the lack of an animal model to evaluate the pharmacokinetics and pharmacodynamics required for the design of clinical trials.

**28.2.3.4.2 Preclinical Studies in Fabry Mice: Proof of Concept.** These obstacles were overcome by the isolation of the human  $\alpha$ -Gal A cDNA (71) and its high-level expression in CHO cells (47), which provided a source of selectively secreted recombinant human enzyme that was highly sialylated and had mannose 6-phosphate residues for lysosomal targeting. In addition, the generation of an  $\alpha$ -Gal A knockout mouse permitted the evaluation of enzyme replacement in an animal model of Fabry disease (48,72). This was the first lysosomal mouse model in which ERT was evaluated. These studies established the pharmacokinetics (i.e. plasma clearance), biodistribution, and pharmacodynamics (i.e. plasma and tissue glycosphingolipid substrate clearance) of the intravenously administered enzyme (48). Of note, subsequent ERT studies in other lysosomal storage disease mouse models resulted in similar findings (49,66,73).

With these advances, preclinical studies of four recombinant human  $\alpha$ -Gal A glycoforms were performed in the enzyme-deficient mice. The pharmacokinetics and biodistributions were determined for each glycoform, which differed in sialic acid and mannose 6-phosphate content (48). The plasma half-lives of the glycoforms ranged from approximately 2–5 min, with the more sialylated glycoforms circulating longer. The tissue distributions of the glycoforms were dose dependent. Following intravenous doses of 0.3–10 mg/kg, each glycoform was primarily recovered in the liver (approximately 30% of dose), with low but increasing levels of each detected in the heart, lung, spleen, and kidney, but not in the brain. Importantly, the accumulated GL-3 was cleared from the liver, heart, spleen, kidney, and plasma in a dose-dependent manner. These studies showed not only that enzyme delivery and GL-3 clearance were dose dependent but also that they determined the rate of GL-3 reaccumulation, which indicated an every-2-week dosing schedule. These preclinical studies provided proof of concept and the pharmacokinetic and pharmacodynamic data critical for the design of clinical trials of enzyme replacement. The optimal  $\alpha$ -Gal A glycoform, AGA-1, was subsequently made by Genzyme Corporation and designated agalsidase beta or Fabrazyme.

**28.2.3.4.3 Clinical Trials of ERT in Fabry Disease.** Trials of ERT in patients with classic Fabry disease have been carried out using recombinant human

$\alpha$ -Gal A produced by two different companies (3,53,74–77). Recent studies comparing the structural and kinetic properties as well as the cell uptake and in vivo pharmacokinetics and biodistribution of the two preparations—agalsidase alfa (Replagal; Shire Pharmaceuticals) and agalsidase beta (Fabrazyme; Genzyme Corporation)—found that the enzyme glycoproteins were similar in their physical and kinetic properties and in their in vivo pharmacokinetics and biodistributions in the mouse model ((78,79); M. Elleder, personal communication, 2005). The only notable differences were the findings that Fabrazyme had three times more mannose 6-phosphate and higher sialylation and that its uptake in the kidney and heart was greater (80,81). A review of published evidence for clinical efficacy of the two enzyme preparations revealed no clear differences in the patients' responses to treatment (82). The clinical trials that provided the evidence-based efficacy for Fabrazyme are described in the following section. These included two multicenter, multinational, randomized, double-blind placebo-controlled studies.

**28.2.3.4.3.1 Phase 1/2 Clinical Trial.** A Phase 1/2 open-label dose-escalation trial involving 15 classically affected males evaluated the safety and effectiveness of five doses of Fabrazyme in dose regimens of 0.3, 1.0, or 3.0 mg/kg every 14 days or 1.0 or 3.0 mg/kg every 48 h (75). The enzyme was well tolerated, and rapid marked reductions in plasma and tissue GL-3 were observed biochemically, histologically, and ultrastructurally. Notably, the clearance of plasma GL-3 was dose dependent (75). Mean GL-3 content decreased by 84% in liver ( $n=13$ ) and was markedly reduced in the kidney in four of five patients who had pre- and posttreatment renal biopsies. Importantly, GL-3 deposits also were reduced in the vascular endothelium of the kidney, heart, skin, and liver by light and electron microscopic evaluations. The trial demonstrated that the dose-dependent GL-3 clearance seen in the preclinical studies was also seen in patients with Fabry disease. In addition, patients reported decreased acroparesthesias, decreased gastrointestinal problems, and increased sweating (75). Thus, these results provided dose-response data and explored the possible primary efficacy end points for a Phase 3 pivotal trial.

**28.2.3.4.3.2 Phase 3 Clinical Trial and Extension Study.** A Phase 3 multinational, multicenter, randomized, double-blind placebo-controlled clinical trial, sponsored by the Genzyme Corporation, evaluated the safety and effectiveness of Fabrazyme in 58 patients who received 1 mg/kg of the enzyme or placebo every 2 weeks for 20 weeks (11 doses) (3). The primary efficacy end point was the percentage of patients whose renal capillary endothelial GL-3 deposits cleared to normal or near normal. In this study, 20 of 29 Fabrazyme-treated patients (69%) cleared the accumulated GL-3 from the renal capillary endothelium versus 0 of 29 placebo-treated patients ( $P<0.001$ ). Compared to the

placebo group, enzyme-treated patients also had markedly decreased microvascular endothelial GL-3 in the skin ( $P<0.001$ ) and heart ( $P<0.001$ ). Patients receiving the enzyme cleared the accumulated GL-3 in plasma to nondetectable levels. Pain and quality-of-life assessments improved in both treatment groups compared to the baseline, indistinguishable from a placebo effect. Note that patients in this study were neither selected for pain nor were pain medications discontinued during the treatment.

All 58 patients completed the Phase 3 trial and received Fabrazyme in an extension study (77). After 6 months of the open-label therapy, 98% of both former placebo-treated and enzyme-treated patients who had biopsies achieved or maintained normal or near-normal renal capillary endothelial histology. Importantly, the GL-3 was cleared to normal or near-normal levels ("0" scores by three independent renal pathologists) in the renal interstitial, glomerular, and nonglomerular endothelial cells, mesangial cells, and interstitial cells after 6 or 12 months of therapy (83). Reduced GL-3 deposits were also histologically documented in the podocytes and tubular epithelial cells (83).

Similar results (i.e. "0" scores) were found for GL-3 clearance in the skin (96%) and heart (75%) in the extension study. Thus, the study confirmed the results of the double-blind Phase 3 trial and demonstrated that the patients treated with enzyme for 12 months had continued GL-3 clearance from the vascular endothelium in the kidney, heart, and skin, the key sites of pathology in this disease. Also, the accumulated plasma GL-3 in the former placebo group decreased to nondetectable levels after 6 months of enzyme treatment. Of note, the mean serum creatinine concentration remained normal (0.8–0.9 mg/dL) without changing from baseline after 12 months of treatment. However, 3 of the 58 patients who were older (42–48 years), had more than 50% glomerulosclerosis (57–100%) and had urinary protein:urinary creatinine ratios greater than 2.0 at baseline exhibited increased their serum creatinine levels. These findings were instructive, as they indicated those patients who already had significant renal disease and whose renal disease would progress, presumably more slowly when treated with adequate doses of ERT (77). Furthermore, these data indicated that ERT was most effective when treatment was started earlier in the disease process, before irreversible damage occurred.

Treatment with Fabrazyme was well tolerated; the adverse event incidence and profiles were similar for both treatment groups in the Phase 3 trial and extension study, except for mild to moderate infusion reactions to the recombinant enzyme, which were managed conservatively. While IgG seroconversion occurred in 88% of enzyme-treated patients, GL-3 clearance was not impaired, and titers decreased with continued treatment. For example, in the Fabrazyme Phase 3 extension study, after 3 years of treatment at 1 mg/kg, in over 50% of

the 58 patients the IgG titers had decreased more than fourfold, and 7 had tolerized. Based on the results of the preclinical and Phase 1/2 and Phase 3 clinical trials, Fabrazyme was approved by the European Agency for Evaluation of Medical Products in 2001 and by the US Food and Drug Administration (FDA) in 2003 (74). Fabrazyme is now approved in over 40 countries worldwide.

**28.2.3.4.4 Clinical Studies of ERT with Fabrazyme.** Since the approval in Europe (2001) and the United States (2003), there have been numerous reports of the clinical benefits of Fabrazyme treatment. These studies have demonstrated the effectiveness of Fabrazyme at 1 mg/kg in stabilizing renal function (84) and improving cardiac function (85–87), gastrointestinal manifestations (88), the Fabry neuropathy (89), and quality of life (90). Of note, Fabrazyme has been administered during hemodialysis without loss of the recombinant enzyme in the dialyate (91). Moreover, Fabrazyme treatment has been shown to improve the quality of life of Fabry patients on dialysis by decreasing pain, improving gastrointestinal symptoms, and slowing or reversing the progressive Fabry cardiomyopathy (92).

**28.2.3.4.4.1 Highlights of the Phase 4 Clinical Trial.** Since the FDA approved Fabrazyme on the basis of a biologic marker, GL-3 clearance from the kidney and other sites, a Phase 4 clinical trial was required by the FDA's Accelerated Approval Program to further confirm the clinical benefit of the treatment. This study was a multinational, multicenter, double-blind placebo-controlled trial involving 82 patients with classical Fabry disease who had mild to moderate renal disease. Patients were randomized 2:1 (Fabrazyme:placebo) at each study site, and the median study time was 18.5 months (35 months total). The primary end point compared the time to the first clinical event (renal, cardiac, or cerebrovascular event or death) between the two treatment groups. After a clinical event, a patient could be switched to open-label enzyme.

This trial showed that, compared to placebo, Fabrazyme at 1 mg/kg every 2 weeks slowed the rate of progression of Fabry disease and substantially reduced the risk of renal, cardiac, and cerebrovascular events together and individually. After the proscribed adjustment for the baseline imbalance in proteinuria between the two treatment groups, patients randomized to Fabrazyme were 53% less likely than the placebo-treated patients to experience a clinically significant renal, cardiac, or cerebrovascular event. Similar to other renal diseases, baseline proteinuria was the most important determinant of outcome. Among the 74 patients who were compliant with the study protocol (the “Per-Protocol” population), after the prespecified adjustment for the proteinuria baseline imbalance between the two treatment groups, the patients who received Fabrazyme were 61% less likely to experience a clinically significant event ( $P=0.034$ ). The most pronounced benefits of Fabrazyme were seen when therapy was started earlier in the course of the

disease (i.e. with less renal dysfunction). These findings emphasize the importance of early treatment with 1 mg/kg of Fabrazyme. In addition, the results of this study were reviewed by the Committee for Medical Products for Human Use of the European Agency for Evaluation of Medical Products (EMA), and based on their recommendation, the label for Fabrazyme in the European Union was changed in August 2005 to include the statement “the results of these studies indicate that Fabrazyme treatment at 1 mg/kg every other week provides clinical benefit on key clinical outcomes in patients with early and advanced Fabry disease. Because this condition is slowly progressive, early detection and treatment may be critical to achieve the best outcomes.”

**28.2.3.4.4.2 Recommendations for Treatment with Fabrazyme.** A group of physicians expert in Fabry disease established consensus recommendations for the diagnosis and treatment of the disease (93). These experts recommended that all males with Fabry disease (including those with end-stage renal disease) and heterozygous females with substantial disease manifestations should be treated with ERT and that the treatment should be initiated as early as possible, particularly in boys with the classical phenotype.

**28.2.3.5 Mucopolysaccharidosis I.** MPS I is an autosomal recessive disorder that results from the absent or deficient activity of  $\alpha$ -L-iduronidase and the accumulation of its glycosaminoglycan substrates, dermatan sulfate and heparan sulfate (for review, see Chapter 102). There are three major phenotypic subtypes, designated Hurler, Hurler–Scheie, and Scheie diseases, whose clinical manifestations range from the infantile onset of severe skeletal, organ, and neurologic involvement and demise in childhood (Hurler) to a later-onset attenuated disorder primarily affecting the liver, spleen, heart, skeleton, and connective tissue, but with no neurologic manifestations or premature demise (Scheie).

**28.2.3.5.1 Phase 1/2 Clinical Trial.** Based on preclinical studies in hound dogs with  $\alpha$ -L-iduronidase deficiency (94,95), an open-label Phase 1 clinical trial of recombinant human  $\alpha$ -L-iduronidase produced in CHO cells (Aldurazyme; BioMarin Pharmaceutical Inc., and Genzyme Corporation) was undertaken in 10 patients (96). After 26 weeks of treatment at a dose of 0.58 mg/kg/week, marked decreases in liver volume and urinary glycosaminoglycan excretion were observed, range of motion improved, and the incidence of sleep apnea and hypopnea decreased. Adverse events included infusion-associated reactions with skin rash, headache, and hives. All patients continued treatment for over 3 years in an open-label extension trial.

**28.2.3.5.2 Phase 3 Clinical Trial.** A multicenter, multinational, double-blind placebo-controlled Phase 3 trial was undertaken with 45 patients (23 patients received enzyme and 22 placebo) who received weekly infusions of either 0.58 mg/kg of enzyme or placebo for 26 weeks (55). The coprimary efficacy end points were pulmonary

capacity (percentage predicted forced vital capacity (FVC)) and a 6-minute walk test (6MWT). Enzyme-treated patients had a mean FVC that was significantly improved over baseline values compared to the placebo group ( $P=0.009$ ), and the 6MWT end point showed a positive trend with an increase of 38.1 m distance in enzyme-treated patients ( $P=0.066$ ). In addition, enzyme-treated patients showed significantly reduced hepatomegaly and urinary glycosaminoglycans. Infusion-associated reactions were managed conservatively. More severely affected patients experienced improved sleep apnea and shoulder flexion. Most patients (91%) developed IgG antibodies to the recombinant  $\alpha$ -L-iduronidase, with no apparent effect on safety or efficacy. In all 45 patients enrolled in an open-label extension study long-term treatment with Aldurazyme led to sustained improvement in FVC and 6MWT (97). Enzyme replacement for MPS I was approved by the FDA in April 2003 (details of the FDA reviews are available at <http://www.fda.gov/ohrms/dockets/ac/cder03.html#EndocrinologicMetabolicDrugs> [Endocrinologic and Metabolic Drugs Advisory Committee of January 15, 2003]) and by the EMEA in June 2003.

**28.2.3.6 Mucopolysaccharidosis VI.** MPS VI (Maroteaux-Lamy syndrome) is an autosomal recessive disorder resulting from the deficiency of arylsulfatase B and the accumulation of dermatan sulfate (for review, see Chapter 102). The disease is characterized by severe skeletal involvement, hepatosplenomegaly, cloudy cornea, and cardiac disease, but no neurologic manifestations.

**28.2.3.6.1 Phase 1/2 and 2 Clinical Trials.** Preclinical studies of ERT were carried out in cats with MPS VI, which demonstrated its effectiveness (98). The development of ERT for MPS VI was sponsored by BioMarin Pharmaceutical Inc. A Phase 1/2 randomized, two-dose double-blind trial of enzyme replacement was undertaken in six patients who received either 0.2 or 1.0 mg/kg/week for 24 weeks and then entered an open-label study (56). All six patients completed 24 weeks of treatment, and five completed 48 weeks. Patients receiving the higher dose had the greatest improvement. There were no infusion-related reactions, presumably because these patients had residual enzyme activity. After 48 weeks of treatment, urinary glycosaminoglycan levels decreased by 51% and 63% in patients who received 0.2 and 1.0 mg/kg, respectively. Five patients who continued in the study had improvement in the 6MWT. One of the three patients with a tracheotomy had an improved FVC, and two had four- to sevenfold decreases in their apnea-hypopnea index. Range of motion improved in all five patients after 48 weeks of treatment.

An open-label multinational Phase 2 trial was conducted with 10 patients who received 48 weekly infusions of 1.0 mg/kg of recombinant enzyme (99). After the 48 weeks of treatment, the mean distance walked in 12 min increased by 138% and the 3-min stair climb showed an average increase of 147% over baseline

values. Joint Pain and Stiffness Questionnaire scores improved by at least 50% by week 24 and were maintained after 48 weeks of treatment. In three of the six patients, improvement in pulmonary function in the absence of growth was observed. In addition, mean urinary glycosaminoglycan levels were decreased by 76% at 48 months (99). Adverse events attributed to the enzyme were generally mild and did not require treatment. IgG antibodies to the enzyme were present in six patients, but were not correlated with adverse events or other safety measures.

**28.2.3.6.2 Phase 3.** A double-blind, randomized placebo-controlled Phase 3 trial involved 39 patients receiving either 1 mg/kg of recombinant enzyme or placebo for 24 weeks. The patients' ages ranged from 5 to 29 years. The primary end point was the change in endurance compared to placebo as measured by the distance achieved in a 12-min walk test. The enzyme-treated patients showed greater increases in the 12-min walk and 3-min stair climbing tests compared to the placebo-treated patients. Based on these results, the drug (Naglazyme) was approved by the FDA in August 2005 and by the EMEA in the European Union in January 2006.

**28.2.3.7 Mucopolysaccharidosis II.** MPS II (Hunter syndrome) is an X-linked recessive disease due to the deficient activity of  $\alpha$ -L-iduronidate sulfatase and the resultant lysosomal accumulation of heparan sulfate and dermatan sulfate (for review, see Chapter 102). There are mild and severe subtypes, both having significant skeletal, organ, and connective tissue manifestations, but differing in the degree of neurologic involvement.

**28.2.3.7.1 Phase 1/2 Clinical Trial.** Based on preclinical studies of ERT in a mouse model of MPS II (100), a Phase 1/2 randomized, double-blind placebo-controlled clinical trial was conducted with 12 patients aged 6–20 years (101,102). The development of ERT for MPS II was sponsored by Transkaryotic Therapies, Inc. (Shire Pharmaceuticals). Doses of 0.15, 0.5, and 1.5 mg/kg were infused every 2 weeks for 6 months, and then patients continued in an open-label extension. In each dose group, three patients received the enzyme, whereas one received placebo. Enzyme-treated patients had reduced liver and spleen volumes and decreased urinary glycosaminoglycan excretions (by 51%). Infusion-related reactions occurred in patients treated with the 0.5- and 1.5-mg/kg doses but were managed with premedication and by reducing the infusion rate. All 12 patients entered the open-label extension study and received the same doses (0.15, 0.5, and 1.5 mg/kg) as in the Phase 1/2 trial. Urinary glycosaminoglycan excretion decreased by 50% and 45% after 6 months and 1 year, respectively, of enzyme therapy in the extension study. Liver and spleen volumes decreased by 27% and 26%, respectively, after 1 year of ERT (61). The 6MWT, a test that integrates the function of the respiratory, cardiovascular, and musculoskeletal systems, increased an average of 48 m after 48 weeks.

**28.2.3.7.2 Phase 3 Clinical Trial.** A double-blind, placebo-controlled multinational Phase 3 clinical trial enrolled 96 patients who received either 0.5 mg/kg of recombinant enzyme or placebo weekly or every other week for 52 weeks (103). A total of 94 patients finished the trial, and all patients enrolled in the open-label extension. The primary end point combined measurements of endurance (the 6MWT) and pulmonary function (FVC). Patients treated with the recombinant enzyme weekly and every other week showed a statistically significant increase in the combined end points over baseline values compared to patients in the placebo group. The group treated weekly with enzyme showed a 37m increase in the 6MWT and a 2.7% increase in percentage of predicted FVC. Treatment was well tolerated, but infusion reactions occurred and antibodies were detected in 46.9% of the patients. Based on these results, a Biologics License Application (BLA) for the drug (Elaprase) was approved by the FDA in July 2006 and in the European Union in January 2007.

**28.2.3.8 Pompe Disease.** This autosomal recessive disease is caused by a glycogenosis resulting from the deficiency of acid  $\alpha$ -glucosidase and the lysosomal accumulation of glycogen primarily in smooth and skeletal muscle. The infantile form of the disease is characterized by massive cardiomegaly, weakness and hypotonia, and death due to cardiorespiratory failure in the first year of life. In contrast, later-onset forms present with progressive muscle weakness and involvement of the respiratory muscles, which can lead to severe respiratory difficulty. Two groups have performed trials of ERT using enzymes produced in the milk of transgenic rabbits or in CHO cells (73,104) (see Table 28-3).

**28.2.3.8.1 Infantile Pompe Disease: Phase 1 and 2 Clinical Trials.** Preclinical trials conducted in acid  $\alpha$ -glucosidase knockout mice that have the myocardial phenotype (73) and the quail model (105) demonstrated proof of concept. Several clinical trials have been performed in infantile Pompe disease and later-onset patients, sponsored by the Genzyme Corporation. The initial pilot studies were conducted in Europe with recombinant human acid  $\alpha$ -glucosidase produced in transgenic rabbit milk (106,107) and in the United States with recombinant human enzyme produced in CHO cells (108). The European study was an open-label Phase 1 trial involving four infantile-onset patients with severe cardiomyopathy. Initially, doses of 15 or 20 mg/kg, and later 40 mg/kg, were infused weekly. At the 40 mg/kg dose, enzyme activity was normalized in skeletal muscle, lysosomal glycogen was reduced and tissue morphology improved in all patients. Cardiac function improved, and left ventricular wall thickness and mass decreased significantly. Patients developed IgG antibodies, and infusion-associated reactions were manageable by slowing the infusion rate. All patients survived beyond the critical age of 1 year, with one patient walking independently and remaining ventilator free as of February 2006.

In a parallel Phase 1/2 open-label study conducted in the United States, three infants received twice-weekly infusions of 5 mg/kg of the recombinant human acid produced in CHO cells for 1 year (108). The enzyme infusions were well tolerated, although two patients were pretreated with antihistamine. Treatment resulted in decreased heart size (left ventricular mass) with maintenance of normal cardiac function. In addition, improved skeletal muscle function was noted. One of the three patients had a good skeletal muscle response, is currently 6.5 years old (as of February 2006), walks independently, and remains ventilator free. Other patients in both studies showed lesser degrees of motor improvement, and most of them eventually became ventilator dependent.

Two additional infantile-onset patients were treated for 22 months with a dose of 40 mg/kg weekly of recombinant human enzyme purified from transgenic rabbit milk (57,109). The improvements in cardiac size and function as well as muscle strength observed in the initial 48 weeks of treatment continued during the 10-month follow-up period (57,109).

Subsequently, an open-label, multicenter trial of eight infantile-onset patients who had cardiomegaly and cardiomyopathy by age 6 months was initiated with the CHO cell-derived recombinant enzyme infused weekly at 10 mg/kg (110). All patients developed nonneutralizing IgG antibodies after 2 months. Three patients died of non-ERT causes. Of the remaining five, all had Alberta Infant Motor Scale scores greater than the third percentile for age, and four were ventilator free. Three patients achieved ambulatory status. All treated patients also had reduced left ventricular mass, and none had signs of cardiac failure. As of February 2006, 8 of the 17 patients in these pilot studies survived past the age of 4 years (111).

**28.2.3.8.2 Infantile Pompe Disease: Pivotal Clinical Trial.** A pivotal clinical trial of recombinant human acid  $\alpha$ -glucosidase produced in CHO cells was conducted in 18 infantile-onset patients under 6 months of age (100). About 83% of the enzyme-treated patients met the primary end point of being alive and ventilator free at 18 months, compared to the historical cohort (only 2%). This higher-than-anticipated positive response when compared with the response of earlier studies was attributed to the initiation of therapy before 6 months of age. However, in a subsequent clinical trial, 21 infants who started at a more advanced age (median age of 13 months) also showed prolonged survival and invasive ventilator-free survival compared with the untreated reference group (112). Based on the results of these successful clinical trials for the infantile-onset form, a BLA for ERT with this enzyme (Myozyme) was approved by the FDA and EMA in April 2006.

**28.2.3.8.3 Later-Onset Pompe Disease: Phases 1/2 and 3 Clinical Trials.** A Phase 1/2 open-label trial was conducted in three later-onset patients (ages 11, 16, and 32 years; two of them being ventilator dependent) with recombinant human acid  $\alpha$ -glucosidase purified from

transgenic rabbit milk (59). Initially, patients received weekly infusions of 10 mg/kg, and then the dose was increased to 20 mg/kg. After 3 years of treatment, their pulmonary functions improved or stabilized. The youngest and least-affected patient, who had been wheelchair dependent for 4 years, started to walk, suggesting that ERT could improve muscle strength, particularly when started early. The other two patients remained wheelchair dependent, but showed improvement in quality of life. No significant infusion reactions were reported.

Another randomized controlled trial in 90 later-onset patients (8 years and older) studied the effect of biweekly infusions of 20 mg/kg of recombinant human acid  $\alpha$ -glucosidase produced in CHO cells (58). After 78 weeks, treatment with the enzyme was associated with improved walking distance (increase of 28 m) in the 6MWT compared to the placebo group and stabilization of pulmonary function (FVC). An independent study of 44 patients with late-onset Pompe disease administered 20 mg/kg enzyme over 12 months showed a similar modest stabilization of neuromuscular deficits (113). Based on these findings, a drug (Lumizyme) was approved by the FDA in May 2010 for Pompe patients who are 8 years and older and who do not have evidence of cardiac hypertrophy. Lumizyme is produced in the 4000-L bioreactor scale and harbors minor differences in glycosylation to Myozyme, which is produced at the 160 L scale.

**28.2.3.9 Niemann–Pick B Disease.** Types A and B NPD result from deficient activity of acid sphingomyelinase (ASM) (114). Type A is the infantile form of the disease and is characterized by severe neurodegeneration that generally leads to death before the age of 5 years. In contrast, most type B patients have little or no neurologic involvement and many survive into adulthood. In these patients, the disease primarily manifests in reticulo-endothelial organs. Intermediate forms of ASM-deficient NPD also have been described.

Recombinant human ASM was produced in CHO cells (115) and used to evaluate ERT in ASM knockout mice (49). These studies revealed that intravenous ASM administration led to the significant depletion of accumulated sphingomyelin and markedly improved pathology in the major pathologic sites, including the spleen, liver, and lung. There was no effect on the progression of brain disease. Preclinical studies also revealed a novel ASM-associated toxicity noted only in ASM knockout mice following high initial doses (>10 mg/kg). Based on these findings, the Genzyme Corporation undertook the clinical development of this therapy for type B NPD. To date, industrial-scale, recombinant human ASM has been produced and characterized, and a large natural history in type B patients has recently been completed. An Investigational New Drug application was submitted to the FDA in 2005, and a Phase 1 clinical trial was completed in 2009. A total of 11 adult patients were administered single ascending doses of intravenous ASM in 5 dose cohorts (0.03, 0.1, 0.3, 0.6 and 1 mg/kg). Dose-related

hyperbilirubinemia, acute phase response and constitutional symptoms were noted between 1 and 3 days post-treatment. The maximum tolerated starting dose was determined to be 0.6 mg/kg. Within-patient dose escalation is proposed as an option for higher repeat doses of the enzyme.

## 28.2.4 ERT: Principles for Effective Treatment

In summary, clinical experience and clinical trials in six lysosomal disorders have demonstrated or indicated the therapeutic effectiveness of ERT. From these studies, certain general principles for effective treatment by ERT have become evident (Table 28-5):

- (1) Intravenously administered recombinant lysosomal enzymes are cleared from the circulation primarily by the pathway mediated by mannose 6-phosphate (mannose in Gaucher disease) receptor for cellular uptake and lysosomal delivery. Thus, the administered enzymes must have their full complement of mannose 6-phosphate residues and be fully sialylated for maximal lysosomal delivery to organs other than the liver, where the hepatocytes will rapidly take up asialo- and galactose-terminated glycoproteins via the asialofetuin receptor (116).
- (2) Dose is important. The higher the dose, the greater is the biodistribution, especially to cell types or sites that have limited uptake, such as the heart and kidney. The recent demonstration of neural uptake and neuronal substrate clearance in the MPS VII adult mice by high-dose enzyme administration clearly emphasizes this principle (66). However, consideration should be afforded to the potential of generating toxic metabolites, as noted in the nonclinical studies in the ASM knockout mice.

**TABLE 28-5 Principles for Effective Treatment for Lysosomal Storage Diseases**

- Enzyme delivery is receptor mediated and dependent on the number of receptors on plasma membrane
  - Mannose 6-phosphate receptor for most lysosomal enzymes
  - Mannose receptor for  $\beta$ -glucocerebrosidase uptake (Gaucher disease)
  - Enzyme: Available mannose 6-phosphate residues
- Avoid galactose residues for asialoglycoprotein receptor
- Inability to cross the blood–brain barrier
- Enzyme delivery is dose dependent
- Substrate clearance is dose dependent
- Adequate dose required for delivery to critical organs
- Off ERT, rapid substrate reaccumulation and clinical exacerbation
- Immune reactions depends on cross-reactive immunologic material (CRIM) status; infusion-associated reactions are manageable
- Treat early to prevent irreversible damage; even in advanced disease, treat to slow/prevent progression

- (3) Substrate clearance is dose dependent.
- (4) There is rapid reaccumulation of substrate if ERT is interrupted or stopped. This was surprising since ERT cleared decades of substrate accumulation, but in the absence of continued treatment, the substrate rapidly reaccumulates. This may be related in part to cell turnover or the proclivity of enlarged “hungry” lysosomes.
- (5) Infusion-associated reactions occur, presumably when patients develop IgG antibodies against the infused recombinant enzyme, but these reactions are transient, can be managed conservatively, and are more frequent in patients with little or no residual enzyme activity. With time, patients may reduce their antibody titers and become tolerized to these enzymes.

Until gene therapy, or another therapy, proves effective in these diseases, ERT provides a safe and effective means to reverse years of substrate accumulation and to control further deposition. A clear need for each of these diseases will be the identification and monitoring of biomarkers that will assess disease progression or improvement, analogous to the use of chitotriosidase activity in type 1 Gaucher disease (78,117,118). Chitotriosidase is expressed by activated macrophages and has been proved to be useful in determining dose requirements in type 1 Gaucher patients (118). Such biomarkers may determine if the initial dose of the enzyme used to debulk years of substrate accumulation can be adjusted to a maintenance dose in individual patients.

## 28.3 SUBSTRATE REDUCTION THERAPY

The aim of SRT is to reduce the amount of noncatabolized substrates in the lysosomes by inhibiting the synthesis of their precursors (for review, see Platt and Jayakumar (18)). The concept, first proposed by Norman Radin for type 1 Gaucher disease, seeks to inhibit the enzyme glucosylceramide synthase that catalyzes the first committed step in the synthesis of glycosphingolipids (17,20). Since its inception, significant progress has been made in identifying small molecule inhibitors of this enzyme with the appropriate safety and efficacy profiles for use in patients with Gaucher disease as well as other glycosphingolipidoses. The potential to deploy small molecule drugs offers the convenience of oral delivery and the potential to have a pharmacodynamic response that is different and potentially complementary to ERT.

As SRT seeks to restore the balance between the rate of biosynthesis and catabolism of the substrates, this therapy is ideally suited for disease populations that retain some residual enzymatic activity. Subjects with type 1 Gaucher disease as well as others with lysosomal storage disorders with a milder disease course typically exhibit this feature. In these patients, SRT can be deployed as a monotherapy; indeed, SRT using miglustat (Actelion Pharmaceuticals) is in clinical practice for treating mild

to moderate type 1 Gaucher disease patients unwilling or unable to receive ERT (119). In subjects who harbor mutations that extinguish enzymatic activity altogether, SRT could be considered in the context of an adjunctive therapy to ERT (120). As miglustat reportedly can traverse the blood–brain barrier into the CNS, it has also been tested in neuropathic type 3 Gaucher disease and NPD type C (22,121).

### 28.3.1 Inhibitors of Glucosylceramide Synthase

Two chemical classes of inhibitor of glucosylceramide synthase are undergoing extensive testing; one is based on the prototypical imino sugar, *N*-butyldeoxynojirimycin (NB-DNJ, miglustat) and the other on *D*-threo-1-phenyl-2-decanoylamino-3-morpholino-1-propanol (eliglustat, Genzyme Corporation) (122).

Early indications that miglustat could effect substrate reduction came from cell culture studies in the presence of conduritol- $\beta$ -epoxide, an agent that inhibits glucocerebrosidase activity and induces the accumulation of glucosylceramide. Treatment of these cells with miglustat abrogated lysosomal storage of the substrate (123). Subsequent studies in mouse models of lysosomal storage disease confirmed the utility of this inhibitor in treating a variety of glycosphingolipidoses including those with CNS involvement. Initial preclinical studies with miglustat were performed in mouse models of Tay–Sachs (19) and Sandhoff diseases (124). Administration of high doses of the drug reduced the rate of accumulation of glycosphingolipids in the visceral organs and brains of these animals. Importantly, in the Sandhoff mice, treatment delayed the onset of behavioral deficits and motor function and extended their longevity by approximately 40%. Efficacy has also been reported in mouse models of Fabry disease (125), GM<sub>1</sub> gangliosidosis (126) and NPD type C (127) that had been treated with the imino sugar. These preclinical studies with miglustat, combined with the earlier clinical experience of this drug in humans with HIV infection (128), encouraged its clinical testing in patients with glycosphingolipidoses.

Characterization of the inhibitory activity of eliglustat on glycosphingolipid synthesis *in vitro* showed that it was more potent and selective than miglustat (79). However, as it is a substrate for the P-glycoprotein multidrug transporter, it does not accumulate in brain tissue and therefore is unlikely to be useful for treating neuropathic lysosomal storage diseases. Testing of eliglustat in a mouse model of type 1 Gaucher disease showed that it reduced the number of Gaucher cells in the liver and the accumulation of glucocerebroside in the liver, spleen and lung. Moreover, Gaucher mice treated sequentially by ERT (Cerezyme) and eliglustat exhibited significantly lower accumulation of glucocerebroside than animals treated with either agent alone (129). Testing of eliglustat either as a monotherapy or combination therapy with

ERT (Fabrazyme) in Fabry mice showed similar benefits (120). These data argue that SRT could function as an adjunctive therapy to ERT for these glycosphingolipidoses. In subjects whose disease has been stabilized by ERT, SRT could potentially be used as a convenient maintenance therapy. In subjects naïve to treatment, ERT followed by SRT could potentially accelerate clearance of the accumulated substrates.

### 28.3.2 SRT for Type 1 Gaucher Disease

The preclinical studies with NB-DNJ in Tay–Sachs and Sandhoff diseases combined with the experience of this drug in human subjects with late-stage HIV infection and AIDS encouraged its clinical testing (miglustat) in patients with type 1 Gaucher disease (21). In a multicenter Phase 1/2 trial, 28 patients with Gaucher disease who had been previously stabilized with ERT were treated with doses of 100 mg three times daily for 1 year. Significant improvements were noted after 12 months, which improved further in patients who elected to enroll in an extension study. Target plasma concentrations of approximately 6  $\mu$ M miglustat were attained, and results showed a decrease in liver and spleen volumes and a progressive decline in the biomarker chitotriosidase. In the extended study period, a clinically significant increase in hemoglobin and platelet counts was also observed (130). These salutary findings were recapitulated in an independent study at another center (131). An additional clinical study that evaluated the use of a lower dose (50 mg three times daily) resulted in a slower therapeutic effect, suggesting a dose-dependent clinical outcome (132). Studies were also conducted to evaluate the merits of switching type I Gaucher patients who have been on ERT to miglustat (133). In this study, 36 patients who were clinically stable on ERT were switched to SRT, maintained on ERT or subjected to a combination of SRT and ERT. After 6 months, no differences in hematological parameters or organ volumes were noted between subjects treated with miglustat or ERT. Based on these observations, it was suggested that SRT was effective for the long-term maintenance of type I Gaucher patients who had previously received enzyme therapy.

The most frequent adverse event was diarrhea due to inhibition of intestinal disaccharidases, which occurred in 79% of the patients. Tremor was relatively common (25% of patients), but this tended to resolve spontaneously or became attenuated with lower doses. Peripheral neuropathy was noted in a small number of patients in the initial trial, which resolved slowly upon withdrawal of the drug, and this feature was absent in subsequent independent trials. Although instances of disturbed cognitive function were also reported, it has not been observed in follow-up monitoring, subsequent clinical trials and pharmacovigilance reports. As preclinical studies in some strains of mice showed that miglustat altered the morphology and mobility of spermatozoa,

these effects have also been recently studied in healthy men (134). No abnormalities in sperm concentration, motility or sperm morphology were noted after 6 weeks of therapy with 100 mg/day of miglustat suggesting the effects on male fertility were species specific. Based on the safety and efficacy profile of miglustat, the drug was approved by the EMA in November 2002 and the FDA in July 2003 for the treatment of adult type I Gaucher patients with mild or moderate disease who are unwilling or unable to receive or to continue ERT.

Based on preclinical studies showing that eliglustat has a higher specificity for glucosylceramide synthase than miglustat and that it does not inhibit the gut glycosidases or glucocerebrosidase, this oral inhibitor has also entered clinical testing in type 1 Gaucher patients. Initial Phase 1 clinical testing of eliglustat in 99 healthy volunteers showed that the drug was well tolerated at doses of 50–200 mg administered twice daily, inducing plasma concentrations within the predicted therapeutic range (135). Plasma glucocerebroside levels were reduced after dosing for 4 days. Mild increases in electrocardiogram PR, QRS and QT/QTc intervals were noted, and inhibition of CYP2D6 is suspected for the nondose-proportional increase in drug levels.

An uncontrolled Phase 2 clinical testing of eliglustat in 26 adult type 1 Gaucher patients showed significant improvements in spleen and liver volumes, hemoglobin concentrations, platelet counts and bone mineral density (136,137). Patients were administered 50 mg or 100 mg of eliglustat twice daily based on plasma drug concentrations, the latter dose to ensure that rapid metabolizers attained concentrations of approximately 10 ng/mL. A composite primary efficacy end point requiring improvement in at least two of three disease manifestations (spleen volume, hemoglobin concentration and platelet counts) was met by 77% of all patients and 91% of the 22 patients who completed the trial at 52 weeks. The magnitude of the hematologic and visceral responses was within the ranges observed with ERT over the same period. However, the increase in lumbar spine bone mineral density was more rapid than with ERT suggesting that cortical bone might have greater access to eliglustat, presumably because of its smaller size. Plasma glucocerebroside and GM<sub>3</sub> levels were normalized and chitotriosidase, CCL18, angiotensin-converting enzyme and tartrate-resistant acid phosphatase levels were decreased by 35–50% relative to baseline. Treatment was generally well tolerated; seven mild transient adverse events in six patients were considered treatment related. Unlike miglustat, gastrointestinal events were low with eliglustat, which is consistent with its lack of inhibition of intestinal disaccharidases, and there was no treatment-related tremor. One patient exhibited asymptomatic nonsustained ventricular tachycardia that was considered possibly treatment related and requiring hospitalization for detailed cardiac telemetry. An analysis of all patients for QTcF interval showed no effect, although minor changes in the PR and QRS intervals were noted.

All 20 eligible patients from the Phase 2 trial elected to continue in the extension period and subsequently into the third year of the trial. Treatment responses observed during the first 52 weeks of eliglustat were confirmed and extended during the second year. Hematological, visceral and skeletal manifestations of type 1 Gaucher disease continued to improve, with no further safety trends emerging over the latter period. Three Phase 3 randomized controlled clinical trials of eliglustat have been initiated. One is in patients who have a confirmed diagnosis and who have not been treated with ERT in the previous 9 months or with an oral therapy in the previous 6 months. Another is designed to compare the efficacy and safety of eliglustat as a maintenance therapy in type 1 Gaucher patients previously stabilized with ERT for at least 3 years. The third trial seeks to compare the effects of a once daily dosing of eliglustat with twice daily administrations.

### 28.3.3 SRT for Other Lysosomal Storage Disorders

As glucosylceramide synthase catalyzes the first committed step in the synthesis of glycosphingolipids; inhibitors of this enzyme may also be considered for treating other glycosphingolipidoses, such as Fabry disease. Preclinical studies in murine models of Fabry disease showed that a dose-dependent reduction in globotriaosylceramide could be attained in several visceral organs (120,138). Moreover, when used in combination with ERT, the effects were shown to be additive. However, an early clinical trial using miglustat (100 mg daily or twice daily) in Fabry disease was stopped as a result of untoward neurological toxicity. Of the 16 males who received the drug 13 developed tremor and 2 complained of paresthesia (139).

As miglustat is reportedly able to traverse the blood-brain barrier into the CNS, it has also been considered for treating lysosomal storage diseases with neurological involvement (140). While initial clinical testing in neuropathic Gaucher type III disease patients suggested a positive effect of miglustat (141), a randomized controlled trial in 30 Gaucher type III patients receiving ERT showed no effect on neurological manifestations (121). Measurements of the aberrant saccadic eye movement that is characteristic of this group of patients as well as neurological and neuropsychological evaluations were not significantly different between the drug-treated and untreated groups. It has been suggested that this failure may be due to the limited potency of miglustat or due to the irreversible nature of the neurological disease in these subjects. Moreover, despite encouraging preclinical data obtained with miglustat in animal models of GM<sub>2</sub> gangliosidosis, an open-label study in 5 patients with juvenile GM<sub>2</sub> gangliosidosis showed that treatment did not alter the progression of neurological disease over a 24-month period (142). However, there was evidence

of reduction of intracytoplasmic inclusions in peripheral blood white cells. A separate study of miglustat in two patients with the infantile form of Tay-Sachs disease there was failure to arrest neurological deterioration over 12 months (143).

Interestingly, SRT with miglustat is reportedly modestly effective in patients with NPD type C. The disorder is characterized by neuronal accumulation of complex gangliosides and neutral glycosphingolipids resulting from a defect in cholesterol and ganglioside trafficking. Treatment of murine and feline models of the disease with miglustat reduced ganglioside accumulation and neuropathology, delayed neuronal dysfunction and increased their lifespan (127). A randomized controlled clinical trial conducted in 29 patients who were 12 years or older showed an improvement in the horizontal saccadic eye movement velocity in patients who received 200 mg miglustat three times daily when compared to those receiving standard care (22). Improvements in swallowing capacity, stable auditory acuity and a slower deterioration in ambulatory index were also noted at 12 months, which were sustained in the majority of patients when analyzed after 24 months (144). Two additional clinical studies in NPD type C patients also showed a stabilization of the neurological disease although the effects were more modest among younger patients who were at a more advanced stage of disease (145,146). Based on these findings, miglustat was approved by the European Medicines Agency (EMA) for treating NPD type C in January 2009. As of March 2010, approval by the US FDA for a supplemental New Drug Application is awaiting additional requests for preclinical and clinical information.

### 28.3.4 Conclusions

It is apparent that SRT is emerging as a competitive alternate therapeutic to ERT. The convenience that this oral therapy offers coupled with the encouraging observations in clinical studies indicate that SRT can represent an advancement in the standard of care for patients with lysosomal storage disorders (LSD). The promise of this technology lies in the development of molecular entities that are able to traverse the blood-brain barrier in quantities that are therapeutic for subjects with neuropathic LSD. This will require an investment either in medicinal chemistry to improve the characteristics of the existing entities or in additional high-throughput screens for new entities with the appropriate drug profile. Now that the concept has been validated, it is also imperative that efforts are expanded to identify drugs for SRT of additional LSD that extend beyond the glycosphingolipidoses.

## 28.4 PHARMACOLOGIC CHAPERONE THERAPY

“Pharmacologic chaperones” are specific, preferably low-molecular-weight, hydrophobic ligands that bind to and

rescue misfolded and/or mistargeted proteins and augment the cell's molecular chaperones to enhance correct folding and organelle targeting of the misfolded mutant conformers. By stabilizing the corrected conformation of the mutant protein, they prevent its degradation. These chaperones may also function by stabilizing a specific conformation of the misfolded protein, reducing aggregation, and/or preventing nonproductive interactions with other resident proteins (for reviews, see Hampton and colleagues (26), Ulloa-Aguirre and associates (25), and Meusser and colleagues (27)).

As proposed for enzymes by Fan and coworkers (147,148), pharmacologic chaperones can diffuse into the cell and bind site specifically to folding intermediates of a mutant enzyme protein, thereby stabilizing the intermediate that is rate limiting for the folding and/or trafficking of the mutant enzyme and rescuing a portion of it from degradation. Competitive reversible enzyme inhibitors can be effective pharmacologic chaperones because of their high affinity to the catalytic domain. Such inhibitors serve as a folding template for those mutant proteins with fragile conformational structures during the protein folding process and induce proper folding. In this way, the pharmacologic chaperone prevents excessive degradation of the misfolded mutant enzyme, which may retain full or partial activity if it can be properly folded, processed, and transported to its normal site of action.

For lysosomal storage diseases, pharmacologic chaperones (active-site-directed reversible enzyme inhibitors) would rescue the misfolded/mistrafficked enzyme that would otherwise be transported by the ERAD machinery to the proteasome for degradation. If even a small percentage of the mutant misfolded/mistrafficked enzymes are rescued, they can be transported to the Golgi for oligosaccharide processing and then delivered to the lysosomes, where the chaperone is displaced by the high concentration of the accumulated substrate(s) (Figure 28-1). It is anticipated that even a small increment in enzymatic activity can markedly attenuate a severe phenotype, as illustrated by the fact that the less-severe subtypes of Gaucher disease and other lysosomal disorders are due to the presence of low levels of mutant enzyme that have very low levels of residual activity (even <1% of wild type). Thus, this therapeutic strategy offers the potential to prevent or effectively reverse the disease manifestations in lysosomal diseases resulting from mutant enzyme misfolding and/or mistrafficking.

The first studies of PCT for lysosomal diseases, carried out in Fabry disease (deficient  $\alpha$ -Gal A activity), demonstrated that mutant  $\alpha$ -Gal A enzymes encoded by various missense mutations could be effectively rescued by various  $\alpha$ -Gal A inhibitors, including 1-deoxygalactonojirimycin (DGJ) (148,149). Subsequently, specific pharmacologic chaperones have been identified for Gaucher,

**FIGURE 28-1** (A) Schematic of the processing, correct folding, and assembly of newly synthesized lysosomal enzymes. The newly synthesized enzyme is translocated into the endoplasmic reticulum (ER), where molecular chaperones facilitate its proper folding and subunit assembly. The molecular chaperones then dissociate from the folded assembled enzyme, which moves to the Golgi apparatus and then to lysosomes, where the enzyme is stable and active in the acidic environment of these organelles. (B) Misfolding and misassembly of mutant lysosomal enzymes. The mutant proteins are retained in the ER and are eventually degraded by the ERAD machinery. Pharmacologic chaperones (yellow triangles) bind to the active site of the enzyme, promote folding, and stabilize the mutant enzyme for proper subunit assembly. This promotes transport of the mutant enzymes to the Golgi apparatus and the lysosomes, thereby increasing the concentration of the mutant enzyme and its residual enzyme activity. (From Fan, J. Q. A Contradictory Treatment for Lysosomal Storage Disorders: Inhibitors Enhance Mutant Enzyme Activity. *Trends Pharmacol. Sci.* 2003, 24, 355.)

Tay–Sachs, and Sandhoff diseases and GM<sub>1</sub> gangliosidosis (150–154). In a murine model of GM<sub>1</sub> gangliosidosis, studies have shown that a pharmacologic chaperone can cross the blood–brain barrier and decrease the neural lysosomal substrate accumulation (152). Recognizing the potential of therapeutic effectiveness of PCT, investigators are evaluating potential compounds as chaperones for other lysosomal storage diseases. In addition, clinical proof of concept has been demonstrated in a patient with later-onset Fabry disease (155). These findings have been translated into the first FDA-approved clinical trial of PCT for a lysosomal disease. A Phase 1 clinical trial of PCT for Fabry disease has been successfully completed (Amicus Therapeutics; <http://www.amicustherapeutics.com>) and a Phase 2 clinical trial is underway (<http://www.clinicaltrials.gov/ct/show/NCT00214500?order=1>).

In the following sections, we provide an overview of the molecular basis of PCT for lysosomal diseases and describe recent *in vitro* and *in vivo* studies that highlight the potential of this therapeutic strategy for lysosomal diseases in which the mutant lysosomal enzyme can be rescued and its stability, delivery to the lysosome, and function increased.

### 28.4.1 Lysosomal Enzyme Biosynthesis and Degradation

Lysosomal proteins are synthesized in the cytoplasm and then secreted into the lumen of the endoplasmic reticulum (ER) in a largely unfolded state. In general, protein folding is governed by the principle of self-assembly (156). Newly synthesized polypeptides and glycopolypeptides fold into their native (active) conformation based on their amino acid sequences in a thermodynamic manner with help from the resident molecular chaperones (binding protein (BiP), calnexin, heat shock proteins (HSPs), etc.). In order to monitor the *in vivo* folding process, the ER has evolved a “quality-control” mechanism, termed ERAD, which uses molecular chaperones to bind and rescue unstable misfolded conformers to facilitate their proper folding and assembly and to prevent the aggregation of nonnative forms through binding and release cycles (13,25,157,158). This machinery ensures that only properly folded and assembled proteins are transported to the Golgi complex for further maturation. Improperly folded proteins are retained in the ER by molecular chaperones and then transported to the cytosol for ubiquitination and degradation within the cytosolic proteosomes (158). In this way, misfolded or unstable (normal or mutant) proteins are eliminated from the cell (158–162). However, even after interaction with molecular chaperones, it is estimated that up to 30% of normal proteins do not achieve their functional state, misfold and/or aggregate, and are rapidly degraded within minutes of their synthesis by the cell’s quality-control machinery (118).

### 28.4.2 Mutations Causing Lysosomal Diseases

Most lysosomal disorders result from a variety of mutations in their respective disease gene that render the encoded enzyme or protein nonfunctional (for review, see Chapter 7). Nonsense and frameshift mutations encode truncated and markedly altered polypeptide sequences that cannot function and are rapidly transported, presumably by the ERAD machinery, to the cytosol for proteosome degradation. Splicing defects result either in no enzyme protein or in an insufficient amount of normal enzyme, which results in substrate accumulation. Certain missense mutations and some small in-frame deletions may not (or minimally) impair the functional domains of the mutant protein (i.e. active site, receptor binding site, etc.) but may cause polypeptide misfolding, aggregation, instability, and/or altered trafficking to the lysosome. Presumably, mutations that cause misfolding slow the normal folding process, thereby resulting in higher concentrations of “folding intermediates,” which can self-aggregate (25,163). Such mutant lysosomal proteins are retained in the ER, where they become associated with molecular chaperones (e.g. calnexin, BiP) that attempt to restore the native conformation or, having failed to form a functional state, undergo rapid degradation by the quality-control system.

In many lysosomal disorders, certain missense mutations produce mutant enzymes that retain a small amount of residual enzymatic activity (even <1%). These missense mutations are associated with the less-severe disease phenotypes. The presence of residual activity presumably results from the small amount of the mutant glycopeptide that was properly folded, assembled, posttranslationally modified, and trafficked to the lysosome. Such mutations are excellent candidates for PCT (see Section 28.4.5). Indeed, even mutations that totally misfold are potentially rescuable by pharmacologic chaperones.

### 28.4.3 Criteria for Rescuable Mutations by PCT

Ulloa-Aguirre and associates (25) have proposed general guidelines to identify rescuable and nonrescuable missense mutations:

- (1) The missense mutation should not alter critical residues essential for ligand binding or substrate/cofactor binding in the case of enzymes that are, predictably, nonfunctional.
- (2) Loss or gain of a cysteine residue may potentially disrupt required sulfuryl bridges or form inappropriate bridges that may be so significantly disruptive to the protein’s structure that rescue cannot occur.
- (3) Loss or gain of a proline residue may limit or even impede pharmacologic rescue, since this amino acid typically causes forced turns in the protein sequence

that may dramatically alter the structure, rendering it nonrescuable. In some proteins, an abrupt turn is likely a requisite for correct structure and cannot be corrected by pharmacologic chaperones.

- (4) Substitutions that impede or promote hydrogen bond formation may reduce the ability of the pharmacologic chaperone to rescue because of the inability of the mutant protein to establish correct interactions between its different domains.
- (5) Substitutions by larger amino acid residues (valine, tryptophan, threonine, and cysteine) may or may not be destabilizing, depending on their position, whereas replacements with smaller residues (glycine or alanine) may allow for more steric freedom and may be accommodated in the folding process, and, therefore, are potentially strong candidates for pharmacologic chaperone rescue.
- (6) If the enzyme or protein has been crystallized, molecular modeling studies can be used to predict the effect of the amino acid substitution on the conformation of the mutant enzyme and the impact on its active site.

For lysosomal enzymes, these pharmacologic chaperones must bind reversibly, so that, when the rescued protein arrives in the lysosomes, the chaperone will be displaced by the high concentration and greater affinity of the already accumulated natural substrate(s). In contrast to ERT with recombinant lysosomal enzymes, the small hydrophobic molecules given orally may cross the blood–brain barrier, diffuse through connective tissue matrices, and reach target sites of pathology that infused lysosomal enzymes cannot, or only can when administered at very high doses. Thus, PCT is particularly attractive for the treatment of neurodegenerative lysosomal diseases.

#### 28.4.4 Experimental Studies of Pharmacologic Chaperone Therapy in Lysosomal Disorders

Most lysosomal storage diseases have less-severe subtypes, resulting from mutations encoding altered enzymes with a small amount of residual activity. Such mutant enzymes are targets for PCT. To identify potential pharmacologic chaperones for lysosomal disorders, investigators have evaluated known or chemically modified substrate inhibitors and analogs or have performed high-throughput screens of chemical libraries (164). These compounds can be evaluated in tissue culture systems or transgenic mice to determine their *in vitro* and *in vivo* ability to rescue certain mutant enzymes (see examples later). PCT may be particularly useful in disorders resulting from common missense mutations that are rescuable, such as  $\beta$ -glucocerebrosidase N370S in type 1 Gaucher disease (153,165),  $\beta$ -hexosaminidase  $\alpha$  chain G269S in chronic Tay–Sachs disease (154), and  $\alpha$ -Gal A N215S in Fabry disease. However, the use of a specific enzyme

inhibitor that binds to the active site has the potential to rescue a variety of missense mutations whose mutant proteins retain residual activity, even less than 1% of the wild type. Experimental studies of PCT in lysosomal diseases are described in this section (Table 28-6). Extension of these studies to mutant enzymes encoded by other missense mutations and to missense mutations encoding mutant proteins in other lysosomal diseases is anticipated.

**28.4.4.1 Fabry Disease.** As noted previously, this X-linked disorder due to deficient  $\alpha$ -Gal A activity has two major subtypes, the severe childhood-onset “classical phenotype” and the later-onset phenotypes, which include the cardiac and renal variants (67,166–169). To date, over 400  $\alpha$ -Gal A mutations have been identified, including missense, nonsense, splicing, and frameshift mutations due to small and large deletions and insertions (Human Gene Mutation Database) (170). In males affected with the classical phenotype, all types of mutations have been reported (67). However, most patients with the later-onset phenotype had missense mutations that encoded mutant enzymes with low levels of residual  $\alpha$ -Gal A activity (167–169).

The crystal structure of human  $\alpha$ -Gal A has been determined, and the location and predicted effect of various missense mutations have been correlated with the observed clinical phenotypes (171,172). Molecular modeling (173) and expression studies (174,175) have been used to characterize the missense mutations and to predict or assess their residual activities.

Previously, galactose, a weak  $\alpha$ -Gal A inhibitor, was shown to stabilize the residual activity of certain  $\alpha$ -Gal A missense mutations, but not others, when these mutant alleles were overexpressed in COS-1 cells (176). Fan and colleagues evaluated a series of  $\alpha$ -Gal A substrate analogs and identified the imino sugar DGJ, a compound that bound to several mutant  $\alpha$ -Gal A enzymes at sub-inhibitory concentrations and most effectively increased their residual activities (147–149). For example, the residual  $\alpha$ -Gal A activities in cultured lymphoblasts from patients with the Q279E and R301Q mutations were enhanced seven- to eightfold after incubation with 20  $\mu$ M DGJ for 4 days. In addition, these investigators generated transgenic mice carrying the rescuable R301Q mutation and demonstrated that the oral administration of DGJ caused a dose-dependent increase in  $\alpha$ -Gal A activity in the tissues of the mice. No toxic effect was observed in transgenic mice treated with DGJ for 140 days (148). Independent studies in R301Q transgenic mouse fibroblasts demonstrated that DGJ treatment released the rescuable R301Q mutant enzyme from the molecular chaperone BiP in the ER. The rescued mutant enzyme was then trafficked via the pathway mediated by mannose 6-phosphate receptor to the lysosome, where it cleared the accumulated GL-3 (177). Thus, these “in vitro” findings indicated that DGJ stabilized the mutant  $\alpha$ -Gal A glycoprotein such that more of the enzyme was transported to the lysosome where it functions.

**28.4.4.1.1 Clinical Proof of Concept: PCT for Fabry Disease.** The clinical efficacy of pharmacologic chaperones for lysosomal disorders has been investigated in the “cardiac variant” of Fabry disease. As noted earlier, patients have residual  $\alpha$ -Gal A activity and an attenuated later-onset phenotype (67,168,169). As proof of concept, a patient with the cardiac variant of Fabry disease who had severe heart disease and was a candidate for cardiac transplantation was treated with galactose, a reversible competitive inhibitor of  $\alpha$ -Gal A. Since galactose is not as effective an inhibitor as DGJ, 1 gm/kg was administered intravenously three times weekly. The infusions were well tolerated, and there was no evidence of hepatic, ophthalmologic, or other side effects. The biochemical, histologic, and clinical effects of the infusions were monitored at 3 months and 2 years of therapy (155). After 3 months of treatment, there was evidence of improvement, and after 2 years of continuous treatment, there was marked improvement in cardiac contractility (an increase in the left ventricular ejection fraction), a moderate reduction in ventricular wall thickness, and a reduction in cardiac mass (Table 28-7). These improvements, which persisted for more than 3 years, were confirmed by the findings of independent observers, by two-dimensional echocardiography, and by cardiac magnetic resonance imaging studies. Cardiac transplantation was no longer required in this patient, because of the clinical improvement (from New York Heart Association functional class IV to class I).

From Frustaci, A.; Chimenti, C.; Ricci, R., et al. Improvement in Cardiac Function in the Cardiac Variant of Fabry's Disease with Galactose-Infusion Therapy. *N. Engl. J. Med.* 2001, 345, 25.

Galactose served as a reversible inhibitor that could bind to the active site and rescue the mutant  $\alpha$ -Gal A protein, thereby promoting the proper folding, dimerization, and processing of the mutant enzyme and preventing the proteasomal degradation of misfolded mutant enzyme glycopeptides (see Figure 28-1). Thus, for patients with the later-onset cardiac variant of Fabry disease whose residual  $\alpha$ -Gal A activity can be enhanced in vitro, active-site-specific PCT may prove safe and therapeutically effective.

**28.4.4.1.2 Clinical Trials of PCT for Fabry Disease.** Based on the preclinical studies in Fabry cultured cells (148), and in transgenic R301Q mice (178), and the clinical proof of concept in the later-onset cardiac variant of Fabry disease (155), efforts are underway to develop PCT for Fabry disease. Under the sponsorship of Amicus Therapeutics, Inc., a Phase 1 safety study was conducted in normal individuals that established the pharmacologic chaperone AT1001's (DGJ) safety in humans and also demonstrated that the rescue of normal  $\alpha$ -Gal A activity was dose responsive (<http://www.amicustherapeutics.com>). Phase 2 clinical

testing of AT1001 in 26 Fabry patients showed a measurable increase in enzyme activity in the leukocytes of 24 patients. In subjects with the greatest increase of enzyme activity, a reduction in substrate load was noted in kidney biopsies. A double-blind, randomized placebo-controlled Phase 3 trial is ongoing to evaluate the efficacy, safety and pharmacodynamics of AT1001 (Amigal) in males and females with Fabry disease. The trial will enroll 60 subjects who are naïve to ERT or who have not received ERT for at least six months prior to the start of therapy with Amigal (150 mg every other day). The primary end point is kidney GL3 levels; secondary end points are urinary GL3 levels, glomerular filtration rate, and safety parameters.

If PCT proves clinically effective for patients with Fabry disease who have residual  $\alpha$ -Gal A activity, investigators will be stimulated to carry out clinical trials of PCT in other lysosomal diseases, particularly those with neurologic manifestations, as described here for Gaucher disease, GM<sub>1</sub> gangliosidosis, and Tay–Sachs/Sandhoff diseases.

**28.4.4.2 Gaucher Disease.** There are three major subtypes of Gaucher disease due to mutations in the approximately 7-kb  $\beta$ -glucocerebrosidase gene that result in absent or markedly reduced enzyme activity (179): type 1, a nonneurologic disorder with clinical onset from childhood to late adult life; type 2, a severe neurodegenerative disorder of infancy; and type 3, a neurologic form with juvenile or late-juvenile onset (179). To date, over 190  $\beta$ -glucocerebrosidase mutations have been identified, including missense, nonsense, splicing, small deletions and insertions, and complex mutations due to crossovers and/or gene conversions involving a pseudogene that is 16 kb downstream from the functional gene (Human Gene Mutation Database) (170,179). Genotype/phenotype studies have revealed that certain mutations have residual activity and are responsible for the nonneurologic type 1 phenotype, whereas others are more severe and occur in the neuropathic type 2 and 3 patients. Several of the  $\beta$ -glucocerebrosidase mutations are common in various populations. For example, the “neuroprotective” N370S mutation occurs in about 70% of alleles in the Ashkenazi Jewish type 1 patients and is also common in European type 1 patients. In addition, the common L444P missense mutation is panethnic and when homoallelic, causes type 3 disease. The crystal structure of  $\beta$ -glucocerebrosidase has been recently determined (180), and studies have attempted to correlate various genotypes with the disease phenotypes (179,181,182).

Recent studies in cultured cells from patients with various  $\beta$ -glucocerebrosidase genotypes have shown that certain mutant enzymes encoded by missense mutations, such as K157Q, D409H, P415R, and L444P, are retained in the ER, where they become bound to calnexin, and are then transported by the ERAD pathway to the cytosol for proteasomal degradation (183). Several of these misfolded enzymes have been the subject of

pharmacologic chaperone rescue by active-site-directed substrate analogs. Lin and colleagues demonstrated that *N*-octyl- $\beta$ -valienamine (NOV) rescued the residual F213I  $\beta$ -glucocerebrosidase activity in cultured cells from type 1 Gaucher patients (151). However, NOV did not rescue other  $\beta$ -glucocerebrosidase mutant enzymes encoded by N370S, L444P, and 84GG.

In contrast, Kelly and colleagues evaluated several substrate analogs of  $\beta$ -glucocerebrosidase and found that *N*-(*n*-nonyl)deoxynojirimycin (NN-DNJ) at subinhibitory concentrations (10  $\mu$ M) led to a twofold increase in the residual activity of the common N370S mutant enzyme (153). Of note, NN-DNJ did not rescue the mutant enzyme encoded by the common more severe L444P missense mutation. The L444P glycoprotein was not rescuable with NN-DNJ either because of the intrinsic nature of the mutant enzyme (less stable, more rapidly degraded, etc.) or because of the alteration of its active site such that the substrate analog bound poorly. Thus, certain mutant proteins for a given enzyme may require different pharmacologic chaperones. However, it is more likely—and attractive—that a particular active-site-directed low-molecular-weight chaperone could bind most, if not all, the mutant proteins with residual activity encoded by the same gene, as has been shown for Fabry disease (J.-Q. Fan, personal communication, 2005). This logic should hold for other mutant proteins with residual receptor, effector, or epitope function. More recently, Kelly and colleagues evaluated 34 potential  $\beta$ -glucocerebrosidase inhibitors to determine if they could rescue the activity of the N370S, L444P, and G202R mutant enzymes in cultured skin fibroblasts. Of these, several compounds increased the activity of N370S and G202R, but not L444P (165).

It is of interest to note that miglustat (NB-DNJ), an inhibitor of ceramide glucosyltransferase used in type 1 Gaucher patients for substrate deprivation, has been studied to determine if it is also a pharmacologic chaperone for  $\beta$ -glucocerebrosidase (150,165). Studies of transfected COS cells with constructs expressing several mutant  $\beta$ -glucocerebrosidase enzymes, including N370S, S364R, V15M, and M123T, had 1.5- to 9.9-fold increases in activity when incubated with 10  $\mu$ M NB-DNJ, whereas the imino sugar did not rescue the activities of the mutant L444P, L336P, and S465del  $\beta$ -glucocerebrosidases, suggesting that NB-DNJ was both a substrate-deprivation molecule for glycolipid synthesis and a pharmacologic chaperone for  $\beta$ -glucocerebrosidase. However, the Kelly group did not find NB-DNJ to have an enhancing or inhibiting effect on the N370S or G202R mutant enzymes in cultured fibroblasts (165).

Thus, several substrate analogs for  $\beta$ -glucocerebrosidase have been shown to serve as pharmacologic chaperones for various mutant enzymes. The prevalence of the type 1 subtype, and particularly the frequency of the N370S mutation, makes Gaucher disease an excellent candidate disease for PCT. Moreover, if a pharmacologic chaperone

can be identified to rescue the L444P mutant enzymes, this therapeutic approach might stabilize or reverse the neurologic manifestations in patients with type 3 disease.

Based on the encouraging preclinical data with isofagamine, an active site inhibitor of glucocerebrosidase, Amicus Therapeutics initiated a Phase 1 clinical trial for Gaucher type 1 disease in 2006. Administration of isofagamine (Plicera) to 54 healthy volunteers was well tolerated and a dose-dependent increase in glucocerebrosidase levels was observed in white blood cells. However, an uncontrolled Phase 2 study in 19 treatment-naïve adult Gaucher type I disease patients failed to demonstrate clinically meaningful improvements in key measures of the disease. Two dosing regimens were studied over a 6-month period. All patients enrolled experienced an increase in the level of glucocerebrosidase activity in their white blood cells, whereas clinical improvements were noted in just 1 of the 18 patients who completed the study. In 2009, Amicus Therapeutics announced that it does not plan to advance Plicera into Phase 3 development.

**28.4.4.3 GM<sub>1</sub> Gangliosidosis.** This autosomal recessive disorder results from the deficient activity of the lysosomal exogalactosidase, acid  $\beta$ -galactosidase (for review, see chapter 104). There are at least three major subtypes, all of which have neurologic involvement because of the accumulation of GM<sub>1</sub>, GA<sub>1</sub>, and related ganglioside substrates (184). The infantile form is a rapidly progressive neurodegenerative disease with demise in the first years of life. The juvenile- and adult-onset forms have residual  $\beta$ -galactosidase activity, but at such low levels that the substrate(s) accumulate, although to a lesser degree in the adult-onset form. To date, over 50 mutations causing GM<sub>1</sub> gangliosidosis have been identified in the  $\beta$ -galactosidase gene (Human Gene Mutation Database) (170), and genotype/phenotype correlations have been proposed (184). The crystal structure of the human enzyme has not been solved.

Suzuki and colleagues reported the pharmacologic chaperone rescue of mutant  $\beta$ -galactosidase activity in deficient human cultured fibroblasts and in a transgenic mouse model of GM<sub>1</sub> gangliosidosis (152). Using the galactose derivative *N*-octyl-4-epi- $\beta$ -valienamine (NOEV), they demonstrated increased  $\beta$ -galactosidase activity in cultured fibroblasts from unrelated patients with GM<sub>1</sub> gangliosidosis. Based on these *in vitro* studies, they introduced a rescuable mutation, R201C, into  $\beta$ -galactosidase-null mice. These transgenic mice were given NOEV *ad libitum* in their drinking water for 1 week (approximately 1.4 mg/day) and then sacrificed. Increased  $\beta$ -galactosidase activity was observed in all tissues, including the brain, as determined by activity assays and histochemical staining. In addition, the accumulated ganglioside substrates GM<sub>1</sub> and GA<sub>1</sub> were decreased in the brain, as shown by immunostaining. These studies indicated that the orally administered pharmacologic chaperone gained access to the brain, rescued the

newly synthesized  $\beta$ -galactosidase mutant enzyme, and decreased the already accumulated substrates in brain lysosomes.

These studies demonstrate that small molecular ligands can rescue a variety of missense mutations and that pharmacologic chaperones can be administered orally and may readily cross the blood-brain barrier, making this approach particularly attractive.

**28.4.4.4 Tay-Sachs and Sandhoff Diseases.** Tay-Sachs disease results from the deficient activity of the  $\beta$ -hexosaminidase A isozyme, and Sandhoff disease results from the deficient activities of both  $\beta$ -hexosaminidase A and B isozymes (185). Both diseases are autosomal recessive disorders (for review, see chapter 104).  $\beta$ -Hexosaminidase A is a heterodimer with  $\alpha$  and  $\beta$ -subunits, each encoded by a different gene.  $\beta$ -Hexosaminidase B is a homodimer of the  $\beta$ -subunit. Mutations in the  $\alpha$ -subunit gene cause  $\beta$ -hexosaminidase A deficiency in Tay-Sachs disease, whereas mutations in the common  $\beta$ -subunit gene result in the deficient activity of both isozymes (185). There are three major subtypes of Tay-Sachs disease: an infantile form that is a severe neurodegenerative disorder with demise typically by 5 years, a juvenile-onset neurodegenerative disease, and a chronic form characterized primarily by progressive ataxia and muscle weakness beginning in childhood or adolescence and later onset of mild to moderate intellectual impairment. The infantile-onset subtype is prevalent in the Ashkenazi Jewish population, with a carrier frequency of about 1 in 25. The less-frequent later-onset form also occurs primarily in individuals of Ashkenazi Jewish descent.

To date, over 100  $\alpha$ -subunit mutations have been identified that cause Tay-Sachs disease (Human Gene Mutation Database) (170). Two common Jewish mutations cause the infantile form: a 4-base exonic insertion and a splicing defect, both of which result in no enzyme protein and the infantile phenotype. In contrast, most later-onset forms result from a common missense mutation, G269S (185,186).

Sandhoff disease also has three major subtypes, the infantile-, juvenile- and adult-onset phenotypes (185). The disease is rare and is not common to any particular population. To date, over 30  $\beta$ -subunit mutations have been identified, and like the respective Tay-Sachs phenotypes, infantile-onset Sandhoff disease results from mutations that produce no stable enzyme protein or activity. In contrast, the juvenile- and adult-onset phenotypes are caused by mutations that have residual activity of less than 5% of wild type (185).

Tropak and colleagues evaluated various known  $\beta$ -hexosaminidase inhibitors to identify a pharmacologic chaperone that could increase  $\beta$ -hexosaminidase  $\alpha$ -chain mutant G269S residual enzymatic activity (7). Of the seven inhibitors tested, *N*-acetylglucosamine-thiazoline (NGT) specifically, and most effectively, increased the amount of mature  $\alpha$ -chain glycopolyptide and

$\beta$ -hexosaminidase activity in the lysosomal subcellular fraction of cultured fibroblasts from a later-onset patient who was homoallelic for the G269S  $\alpha$ -chain mutation. Increasing concentrations of NGT in the growth media resulted in higher residual activity with days in culture and was not toxic to the cells. Similarly, NGT was able to enhance the  $\beta$ -hexosaminidase  $\beta$ -chain P504S mutant enzymatic activity in fibroblasts from a patient with adult-onset Sandhoff disease. Thus, these studies demonstrated that NGT bound to and stabilized the mutant enzymes in the ER, resulting in increased amounts of mutant enzymes that exited the ER and were transported to the lysosomes, where they could function at their preferred acidic pH.

### 28.4.5 Criteria for Selection of Pharmacologic Chaperones

Implicit in the selection of a pharmacologic chaperone for the treatment of patients with a lysosomal or other disease is the demonstration that the compound is nontoxic, is readily eliminated in the urine so it or its metabolites do not accumulate, and optimally rescues a variety of disease-causing mutations. In addition, molecules that could function as pharmacologic chaperones should be cell permeable and have the ability to reach the ER and remain undegraded/unmetabolized long enough to stabilize the target mutant protein and transport it to the lysosome (25). For neurodegenerative disorders, the compound must be able to reach sufficient concentration in the brain. Finally, clinical studies must demonstrate long-term safety, biochemical effectiveness (increased enzymatic activity and/or substrate clearance), and clinical benefit without adverse reactions.

### 28.4.6 Pharmacologic Chaperone Therapy for Nonlysosomal Diseases

Pharmacologic chaperones have been sought and/or evaluated for a variety of nonlysosomal diseases (Table 28-8). These include disorders such as Alzheimer disease (187) and retinitis pigmentosa (188), in which there is mutant protein misfolding and aggregation, and other diseases such as cystic fibrosis (188) and nephrogenic diabetes insipidus (189), in which there are both protein misfolding and trafficking defects. Pharmacologic chaperones have been the subject of recent reviews (1,23,25,147,190–194).

## 28.5 CONCLUSIONS AND FUTURE DIRECTIONS

The past 15 years have seen remarkable changes for scientists and clinicians working on lysosomal diseases. The era of lysosomal disease treatment has led to new awareness of these disorders and renewed excitement among researchers and patients. ERT is available for

**TABLE 28-8 Pharmacologic Chaperones: Rescue of Misfolded Proteins in Genetic Diseases**

Disease	Defective Protein
<b>Lysosomal enzymes</b>	
Fabry disease	$\alpha$ -Galactosidase A
Gaucher disease	Acid $\beta$ -glucosidase
<b>Channel proteins</b>	
Cystic fibrosis	CFTR
Long QT syndrome	HERG K <sup>+</sup> channel
<b>Receptor defects</b>	
Nephrogenic diabetes insipidus	Vasopressin V <sub>2</sub> receptor
Retinitis pigmentosa (autosomal dominant)	Rhodopsin
Familial hypercholesterolemia	LDL receptor
Hypogonadotropic hypogonadism	Gonadotropin-releasing hormone receptor
<b>DNA transcriptional protein</b>	
Cancer	p53
<b>Conformational diseases</b>	
ATT deficiency	$\alpha_1$ -Antitrypsin
Amyloidoses	Transthyretin

Based on Fan, J. Q. A Contradictory Treatment for Lysosomal Storage Disorders: Inhibitors Enhance Mutant Enzyme Activity. *Trends Pharmacol. Sci.* 2003, 24, 355.

six disorders (Gaucher, Fabry and Pompe diseases and MPS I, II and VI), and is under development for several others. Experimental and clinical experience with other approaches, including bone marrow transplantation, substrate deprivation, and gene and stem cell therapies, have identified their useful applications and limitations (2,3,6,7,28). However, despite these remarkable advances, significant hurdles still remain before the goal of treating all or most lysosomal diseases can be realized. Primary among them is the need to treat the neurodegenerative lysosomal diseases.

PCT represents an attractive new strategy that uses small molecules that can be administered orally to rescue misfolded/mistargeted lysosomal enzymes (or other proteins), thereby resulting in their increased activity and therapeutic benefit. In addition, PCT offers the possibility of treating disorders with neurologic involvement, since low-molecular-weight pharmacologic chaperones may be designed to cross the blood–brain barrier. It is likely that PCT strategies may have a significant therapeutic effect; however, the treatment will be limited to patients with rescuable mutations. It is important to note that pharmacologic chaperones may have markedly different biodistributions than replaced recombinant human enzymes, whose tissue delivery is primarily dependent on their respective receptor-mediated delivery and that do not cross the blood–brain barrier. Thus, for certain diseases, combined PCT and ERT may be beneficial, particularly for the treatment of neurodegenerative lysosomal and other diseases of the CNS. In summary,

it is anticipated that the early years of the twenty-first century will witness the development of safe and effective ERT and PCT for patients with lysosomal and other inborn errors of metabolism.

## ACKNOWLEDGMENTS

This work was supported in part by grants from the National Institutes of Health, including research grants R37 DK34045, R01 HD28607, R01 DK25759 and R01 DK54830 and a grant 5 MO1 RR00071 to the Mount Sinai General Clinical Research Center Program from the National Center of Research Resources.

### Biographies

**Robert J Desnick, MD, PhD**, is Dean for Genetics and Genomics and Professor and Chairman of the Department of Genetics and Genomic Sciences at The Mount Sinai School of Medicine as well as Physician-in-Chief of the Department of Medical Genetics and Genomics at the Mount Sinai Hospital in New York City. He is board-certified in clinical, biochemical, and molecular genetics by the American Board of Medical Genetics and is a Fellow of the American Academy of Pediatrics. He has published over 600 research articles and chapters, including nine edited books. He is a founder and Past-President of the Association of Professors of Human and Medical Genetics and is a past Chair of the Association of American Medical Colleges (AAMC). He is an elected member of the American Pediatric Society, American Society for Clinical Investigation, American Association of Physicians, American Academy for the Advancement of Science (Fellow), and the Institute of Medicine of the National Academy of Sciences.

**Kenneth H Astrin, PhD**, is an Associate Professor of Preclinical Sciences at the New York College of Podiatric Medicine and Professional Lecturer in the Department of Genetics and Genomes, Mount Sinai School of Medicine, New York. He received his BA in Biology in 1966 from the University of Chicago and his PhD from the Department of Biology, University of California, San Diego in 1973. His postdoctoral research was performed in the Department of Medicine, Baylor College of Medicine, Houston, Texas, and in the Division of Genetics, Mount Sinai School of Medicine, New York. In 1981, Dr Astrin was first appointed to the faculty in the Division of Genetics, Mount Sinai School of Medicine, New York and later was appointed to the position of Associate Professor in the Department of Genetics, Mount Sinai School of Medicine, New York in 2000. In 2007, Dr Astrin became Associate Professor of Preclinical Sciences at the New York College of Podiatric Medicine where he teaches Biochemistry, Introduction to Human Genetics and Molecular Biology/Molecular Genetics courses. Dr Astrin's research interests include Fabry disease and the inherited diseases of heme biosynthesis, the porphyrias. He is the coauthor of 32 refereed scientific articles.

**Seng H. Cheng, PhD**, is Head of Research and Early Development of the Rare Diseases Division at Genzyme, a Sanofi Company. Prior to Sanofi, he was Group Vice President of Genetic Diseases Science at Genzyme Corporation where he worked on several discovery projects including the structure and function of the cystic fibrosis transmembrane conductor regulator. At Genzyme, he also managed the development of novel gene delivery vector systems and more recently, the translational research activities in genetic diseases. Areas of focus included inherited metabolic (e.g. lysosomal storage disorders), muscle, lung and neurodegenerative diseases. Dr Cheng received his BSc and PhD degrees in Biochemistry from the University of London, U.K. He trained as a postdoctoral fellow at the National Institute for Medical Research in London, U.K. and at Integrated Genetics Inc. He has published over 200 scientific research articles and is a co-author on 41 issued patents in the area of biotechnology. In his current position, he is responsible for directing and managing the research and early development activities in rare diseases.

**Dr Schuchman**, PhD, is The Genetic Disease Foundation, Francis Crick Professor and Vice Chairman for Research in the Department of Genetics and Genomic Sciences at the Mount Sinai School of Medicine and holds a secondary appointment in the Department of Gene and Cell Medicine. He received his BS degree in Biochemistry from Stony Brook University in 1979 and his PhD in Human Genetics from Mount Sinai in 1983. After completing a postdoctoral fellowship at Yale University, Dr Schuchman returned to Mount Sinai as a faculty member in 1986. His laboratory has been studying the biology of lysosomal enzymes and storage diseases for over 25 years, resulting in the first isolation of the genes encoding several lysosomal enzymes, including acid sphingomyelinase, arylsulfatase B, and acid ceramidase. Based on his work, clinical trials of enzyme replacement therapy for type B Niemann–Pick disease are currently underway. The NIH has funded Dr Schuchman’s research for over 25 years, and he has published over 150 peer-reviewed research articles. In 2003, he was awarded the Mount Sinai Faculty Council Award for Academic Excellence and in 2008, the Dean’s Award for Translational Science. He also is a reviewer for many scientific journals, serves on grant review committees, and is on the advisory boards for foundations.

### 29.1 GENES AS MEDICINES— THE ORIGINS OF GENE THERAPY

The identification of most genes that makeup the human genome makes it easy to think about the potential medical applications of genomics. Cutting a gene out and using it to replace a missing one does not sound like science fiction anymore. However, the idea of using genes as medicines was born too early. In fact, it was proposed before it was straightforward to identify individual genes within genomes and before the discovery of restriction enzymes, i.e. before cutting and pasting in the genome was possible. Thus, the first experiments were primitive by today's standards, and literally stopped while the technologies of molecular biology were being discovered.

In the early 1970s RNA oncogenic viruses were shown to cause cellular transformation through the insertion of viral genomic sequences into the infected host cell genome. Around the same time, scientists were discovering that many inherited diseases were caused by mutations in single genes. They thus reasoned that if genes could be isolated from normal nonmutated human genomic sources and inserted into RNA viruses in lieu of their wild-type oncogenes, and these modified viruses

then used to transfer the normal genes into the cells and tissues of affected patients, inherited diseases could be treated directly by gene transfer. Thus, gene therapy was envisioned.

Realizing these ideas had to wait many years before restriction enzymes, routine sequencing and the manipulation of viral genomes became easily accessible. Interestingly, during this incubation stage, scientists discussed the ethical boundaries of gene therapy as well as the foundations for the ethical and scientific review of potential future clinical trials in gene therapy. The Food and Drug Administration established a Cell and Gene Therapy section, and the National Institutes of Health created the Recombinant DNA advisory committee to review the science and ethics of future clinical trials in gene therapy.

The establishment of the function of the regulatory bodies was crucial because earlier attempts at gene therapy were marred by unclear overview powers. Early attempts by Martin Cline from UCLA to transfer a globin gene and thymidine kinase into blood and/or bone marrow cells from patients suffering from sickle cell anemia were carried out abroad, in Italy and Israel, before the existence of either of the regulatory agencies. Although this trial occurred outside the United States and had local ethical approval, the use of reagents produced under US federal oversight and funding and the absence of federal US approval for this trial effectively ended the scientific career of the Chair of Haematology-Oncology at UCLA.

From then onward guidelines were developed to usher the era of genetic medicine in the United States, and thus, the rest of the world Figure 29-1 for the evolution of gene therapy, and Figures 29-2 and 29-3 for the most common vectors in clinical use and the diseases being treated.

## 29.2 THE BASIC SCIENCE: GENE TRANSFER (TABLES 29-1–29-3)

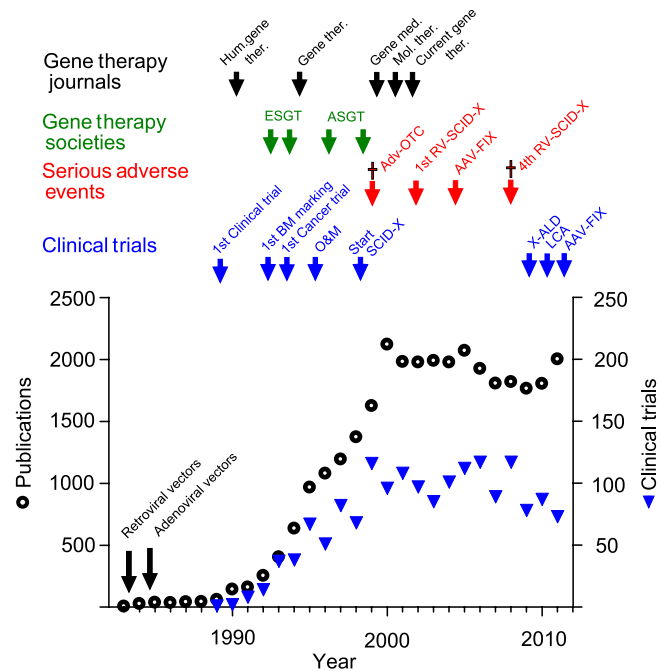

### 29.2.1 Retroviral and Lentiviral Vectors

Viruses are very effective in transferring their own genes into eukaryotic cells and have been adapted as Trojan horses to deliver therapeutic DNA sequences into affected cells. Retroviruses were the first vectors developed. Vector genomes were engineered to remove sequences encoding for pathogenic functions and generally to abolish the replication of the parent wild-type viruses (1–3).

Retroviruses are enveloped single-stranded RNA viruses and have been widely used in gene transfer and gene therapy. Retroviruses have a genome of about 7–10 kb, composed of three gene regions termed *gag*, *pol* and *env*. These gene regions encode structural capsid proteins, the integrase and viral reverse transcriptase, and envelope glycoproteins, respectively. The genome also has a packaging signal ( $\Psi$ ) and cis-acting sequences, termed long terminal repeats (LTRs), at each end, which have a role in transcriptional control and integration of the viral DNA into the infected cell's genome (4–6).

The retrovirus life cycle is initiated by the interaction of the viral envelope protein with one or more specific receptor molecules located on the plasma membrane of target cells (7). Following entry into target cells, the RNA is reverse transcribed into linear double-stranded (ds) DNA by the viral reverse transcriptase and subsequently integrated into the cell chromatin by the viral integrase. One of the most important properties of retroviruses is their ability to integrate into the genome of target cells, ensuring stable transduction and potential long-term gene expression. Integration of the simpler retroviruses only occurs in dividing cells, since retroviruses use the mitotic breakdown of the nuclear membrane to access the host cell chromosomes. Lentiviruses, a group of more complex retroviruses, have evolved the capacity to cross the intact nuclear membrane and thus integrate into nondividing cells. This is particularly useful for transducing the neurons of the central nervous system (CNS), which cannot be transduced by retroviral vectors but can be transduced well with lentiviral ones (8).

In order to make retroviral vectors carrying therapeutic genes the *gag*, *pol* and *env* genes are removed. This provides a space of up to 8 kb for exogenous DNA to be inserted. The products of the deleted genes are required for the production of functional retroviral vectors,

**FIGURE 29-1** Illustration of the yearly number of publications that mention “gene therapy” in the title or abstract from the PubMed database compared with the number of clinical gene therapy trials, taken from the Journal of Gene Medicine database. Above the figure, starting dates of the first and subsequent significant clinical trials are indicated in blue and reports of the most serious adverse effects are given in red. In addition, we have shown the appearance of International Gene Therapy Societies, and the most important journals in the field. The first clinical trials in gene therapy were those performed by Malcolm Brenner and collaborators in Memphis on bone marrow marking and the treatment of ADA-deficiency. “O&M” indicates the publication of the Orkin and Motulsky (256) report on the status of gene therapy that recommended a return to the basic science. “Start SCID-X” refers to the trial conducted by Alain Fischer and collaborators in Paris, accepted as the first-ever conclusive “cure” achieved by gene therapy (257). “X-ALD” indicates the successful treatment of X-linked adrenoleukodystrophy (133). “LCA” indicates the successful treatment of Leber’s congenital amaurosis (134) and “AAV-FIX” in blue indicates the successful treatment of hemophilia (258) “+Adv-OTC” in red indicates the death of J. Gelsinger during the clinical trial for ornithine transcarbamylase deficiency at the University of Pennsylvania (259). “1st RV-SCID-X” indicates the first of four times that leukemia was diagnosed in each of the affected patients treated for SCID-X in Paris (A fifth patient was diagnosed with leukemia during a trial in London). “AAV-FIX” in red indicates the description of the loss of transgene expression and transient hepatitis in one patient treated with AAV-FIX for hemophilia in the trial led by Kay and High in Stanford and Philadelphia (245). “4th RV-SCID-X” indicates the report of the death from refractory leukemia of one of the patients in the Paris SCID-X trial (By this time the remaining three patients diagnosed with leukemia in this trial and the single patient who developed leukemia in the London trial have all been successfully treated and have been in remission for several years).

however. Therefore, these proteins are provided in *trans* by packaging cell lines expressing the *gag*, *pol* and *env* genes but lacking most viral cis-acting regions. The use of packaging cell lines reduces the risk of generating replication-competent retroviruses (RCR) by homologous recombination events between the viral plasmid

and the packaging cell line. The current generation of “safe” packaging cell lines involves them carrying two to three separate constructs, one of which expresses the

**FIGURE 29-2** This figure divides the clinical trial described in Figure 29-1 by diseases treated and whether they were early Phase I or more advanced Phase III trials. Notice that most trials are for cancer and most are Phase I toxicity trials.

**FIGURE 29-3** This figure indicates the vectors used for the clinical trials represented in Figure 29-1. Notice that retrovirus, the very first viral vectors developed, and adenoviruses continue to be the most common vectors in clinical use.

gag and pol protein and the second that expresses the env protein. Alternatively, each gene may be carried by separate plasmids. Expressing each gene from a different plasmid improves the biosafety by increasing the number of recombination events required for the generation of RCR (9–11).

Further developments to improve the efficacy of retroviral vectors have been the generation of “pseudotyped” vectors. Pseudotyped vectors carry the genetic information, the core of one virus, and an envelope containing the env protein of a different one. Pseudotyped viruses have thus a different host range. Use of the envelope protein of viruses with a very narrow host range, such as HIV, allows to target gene delivery to particular cell types, but for other applications, a broader cell tropism is desirable. For example, vectors pseudotyped with the G glycoprotein of the vesicular stomatitis virus (VSV-G) can infect most cell types, are particularly stable and can be concentrated to titers exceeding  $1 \times 10^8$  TU/mL. VSV-pseudotyped lentiviral vectors efficiently transduce neurons and glial cells of the CNS of rodents. Stable long-term transgene expression was observed without any major vector-associated toxicity (8,12).

One of the newer retroviruses used for gene therapy vectors are the lentivirus. Lentiviral vectors are derived from human immunodeficiency virus type-1 (HIV-1), feline immunodeficiency virus (FIV), or the equine infectious anemia virus (EIAV). Vectors derived from viruses that are nonpathogenic in humans, such as EIAV, have an obvious safety advantage. Lentiviral vectors transduce and integrate into dividing and nondividing cells in vitro and in vivo (8,13,14). Lentiviral vectors can integrate into the genome of postmitotic cells, such as neural cells, monocytes and hematopoietic bone marrow, and stem cells (15,16).

To develop HIV-derived vectors, initially, accessory genes (vif, vpr, vpu and nef) that are not essential for

Microinjection Transfection <sup>a</sup>	<ul style="list-style-type: none"> <li>• Difficult to introduce DNA on a scale large enough for biochemical analysis</li> <li>• Targeting is not specific</li> <li>• Low transfection efficiency</li> <li>• Only transient expression</li> <li>• Difficult in vivo applications</li> <li>• Host immune responses: inflammatory reactions in patients if vectors express chimeral cell receptors on their surface, or in the presence of unmethylated CpG sequences of bacterial plasmid DNA</li> </ul>

<sup>a</sup>Cationic liposomes or DNA-protein complexes.

transduction were eliminated (17). Second, a three-plasmid expression system was used to minimize the possibility of generating replication-competent virus through recombination (8). Third, self-inactivating (SIN) vectors

were engineered by deletions in the 3' LTRs of the HIV-1 vectors. SIN vectors also facilitate regulated expression of genes from internal promoters by reducing cis-acting effects of the HIV-1 LTR (18,19).

Retroviruses are the vectors of choice for *ex vivo* gene therapy, such as diseases that can be treated by replacing a gene within bone marrow cells, such as the blood disorder ADA deficiency, various leukodystrophies, and SCID-X (see below). For *ex vivo* gene therapy, bone marrow hematopoietic precursor cells are removed and infected *in vitro* with retroviral vectors. Clones will be selected and those expressing the highest levels of transgene expression will be used to transplant back into the patients. This procedure selects for clones with a clear growth advantage resulting in the transplantation of those clones with the highest growth rates. The functional implications of this will become clearer when reviewing some of the side effects due to the integration sites of the retroviral genomes.

For a long time it was thought that retroviruses integrated randomly into the host cell's genome. Recent detailed analysis of integration sites, using the knowledge gained from the human and mouse genome projects, has shown that although there is no site-specific integration of retroviral vectors, they do integrate preferentially into areas of the genome containing highly active or transcribed genes. This results in the existence of hotspots for genomic integration. How these integration sites affect the expression of the genes located nearby has only been studied in detail in the case of the patients who developed leukemia post gene therapy during the treatment of SCID-X.

Newer developments concern targeted vectors that will selectively infect predetermined cell types and the use of cell-type-specific and inducible promoter systems, advances that are now being applied to most available vector systems. Also, a number of groups have recently described the use of replication-competent retroviral vectors. These have been applied particularly to the treatment of brain tumors. Brain is made up of a majority of nondividing or very slowly dividing populations of cells; therefore, brain tumors constitute a population of highly mitotically active cells within an organ built essentially from nondividing ones. Therefore, replication-competent retroviral vectors, in principle, would be able to replicate specifically throughout the brain tumors, without damaging healthy brain cells such as the neurons and the astrocytes. In this case the replication competency of the vectors is what allows them to specifically reach the intended target, namely, the brain tumors (20,21).

Tai et al., (22) reported that a replication-competent retroviral vector derived from murine leukemia virus encoding the suicide gene yeast significantly extended the survival of mice with experimental glioma, and this treatment is currently the subject of a Phase I clinical trial.

### 29.2.2 Herpes Simplex Virus

Herpes simplex virus (HSV) can infect and express genes in both dividing and nondividing cells (23–25). It is a

large neurotropic human virus containing 152kb of linear ds DNA that naturally establishes lifelong asymptomatic infections of the nervous system with periodic epidermal manifestations, without the need of integrating the viral chromosome into the host genome. It can cause a virulent lytic infection or stay latent in the CNS (26). Episomal HSV genomes can reactivate, causing dermal lesions. The neurotropism of this virus has prompted the development of vectors for gene delivery to the nervous system (for a review of the use of HSV-derived vectors in brain disease, see Marconi et al., (27)). The HSV viral genome consists of unique long (UL) and unique short (US) regions, which encode gene products that regulate gene expression, DNA replication and structural proteins that form the viral capsid and the tegument. The genome also contains several cis-acting regions, including origins of replication and sequences within the terminal repeats, which are essential for packaging of genomes into virions (24). After infection of animal cells, a cascade of viral gene products is expressed that leads to the production of progeny virus. In neurons, HSV vectors are delivered by rapid retrograde transport along neurites to the cell body. The viral DNA is deposited in the nucleus, initially in a circularized episomal form, and eventually replicates and enters latency. During latency no proteins are expressed; however, a few mRNAs are expressed under the control of the latency (LAT) promoter. The expression of these LAT transcripts is driven by two adjacent promoters known as LATP1 and LATP2. Long-term transgene expression (up to 6 months) has been shown when the LATP2 promoter is used (28). The ability of viral particles to move along neural processes provides an indirect approach for targeting gene transfer to cells that are difficult to reach directly, but whose terminal fields are accessible, such as dorsal root ganglion neurons that can be reached from their axonal terminals in the skin.

Two types of vectors are derived from HSV: recombinant viral vectors (rHSV) and amplicon vectors. rHSV contain the full viral genome mutated in one or more viral genes to reduce toxicity and provide space for transgenes in the range of 30–50kb. In order to generate rHSV it is important to remove virally encoded cytotoxic functions produced during the lytic cycle and promote the establishment of latency. Early rHSV vectors involved the deletions of ICP4 and ICP27, which effectively block viral replication and promote the entry of the HSV genome into latency (29,30). These viruses are grown on specially constructed cell lines that encode the genes that are missing *in trans*. Unfortunately, these early rHSV were shown to be highly toxic because of the continued synthesis and accumulation of other IE gene products (29). rHSV vectors can enter a stable, nontoxic, episomal latent state in neurons but with consequent down-regulation of most viral and cellular promoters (31). The use of various latency promoters to drive

transgene expression has allowed the maintenance of transgene expression during latency.

It has been shown that rHSV vectors deleted of all viral genes are essentially silent, except for transgene expression (32). An important modification of rHSV vectors for in vivo gene transfer into postmitotic cells has been the generation of vectors lacking the ICP34.5 gene. These viruses are incapable of growing on nondividing cells, although they can be grown in culture on dividing cells (33). These vectors were effectively utilized in the very first clinical trials of HSV-derived vectors in clinical gene therapy. HSV-1716, an ICP34.5-deleted HSV1-derived vector, has been evaluated in three Phase I trials for glioma (34), and a Phase II trial is currently being developed. G207, which, in addition to ICP34.5 deletion, has an additional deactivating insertion, lacZ insertion in UL39, has been used in two clinical trials for glioma (35).

An alternative HSV vector system is the “HSV amplicon.” The amplicon system relies on introducing the gene of interest into a plasmid, which has an HSV origin of replication and packaging signal. This construct is then introduced into cells by transfection. The cells are then infected with a helper HSV virus resulting in the amplicon becoming packaged into the virus particle (36). The advantages of these vectors are that they are essentially nontoxic or antigenic, as they express no virus proteins, although they generally contain low levels of contaminating recombinant replication-competent virus during packaging. They also have

a large transgene capacity (theoretically up to 150 kb), relatively high titers (up to  $10^8$  ti/mL with the current packaging modalities), high infectivity for cells of the nervous system and retention for several months in nondividing cells (31). Amplicon vectors have yet to be tried in humans but have shown some promising preclinical results (37).

### 29.2.3 Adenovirus Vectors

The major clinical interest in adenovirus vectors (AdVs) stems from their broad host range, high infectivity for most cells in the human body and the ability to infect quiescent and dividing cells. Adenoviruses belong to the family Adenoviridae, and to date human adenoviruses are found as 47 different serotypes. The viruses are grouped together into six subgroups termed A–F according to physical and pathological properties. The most commonly studied serotypes are 2 and 5, and they have been widely studied to determine adenovirus biology and have also been exploited for the development of gene transfer vectors.

Adenoviruses are medium-sized, nonenveloped viruses having 36-kb ds DNA and icosahedral particles that are approximately 80 nm in diameter (Figure 29-4). The adenovirus consists of a protein capsid surrounding a core containing the ds DNA genome. The protein capsid is composed of 252 protein subunits (capsomeres), of which 240 are hexons and 12 are pentons. As suggested by their names, penton and hexon subunits are

## Adenoviral vectors

**FIGURE 29-4** Schematic view of AdVs. The top left image illustrates an adenoviral capsid in three dimensions and the constituents are indicated in the top right figure. Below, the genomes of a first-generation vector (e.g. RAD35, only lacking the E1 and E3 region is illustrated) and a novel high-capacity helper-dependent vector (AdGS46), lacking all wild-type adenovirus genomic sequences, are shown.

surrounded by five and six neighbors, respectively. Each penton is composed of a penton base and a projecting fiber located at the vertices of the icosahedral capsid (Figure 29-4). The Adenovirus genome is functionally divided into two major non-contiguous overlapping regions, early and late, defined by the onset time of transcription after infection. The viral chromosome is further divided into five early coding regions (E1a, E1b, E2, E3, and E4), two intermediate transcription units (pIX and Iva2) and one major late region (MLR) that consists of five principal coding units (L1–L5). The MLR encodes the information for capsid and internal core structural proteins. An additional region of the chromosome is transcribed by RNA polymerase III and encodes two virus associated RNAs, one of which acts to prevent inhibitory phosphorylation of the cellular elongation factor eIF-2 and thus maintain protein translation in spite of a cellular interferon response (38). Other features of the genome include the inverted terminal repeats (ITRs) located at the end of the viral chromosome, which act as the origin of replication. Preceding the ITR is a  $\Psi$  sequence, which encodes the packaging signal (39).

Adenovirus infects cells by binding to cell surface receptors, mediated by the interaction of the penton fiber protein with the coxsackie adenovirus receptor (CAR) (40) and the binding of the penton base with cellular integrins,  $\alpha_v\beta_5$ . Binding to the cell surface receptors leads to the internalization of the virus via clathrin-coated pits (39), followed by internalization and endosome exit. The nucleocapsid is transported to the nucleus via a microtubule-dependent process, followed by the translocation of the Ad genome across the nuclear membrane by an ATP-dependent process where viral DNA synthesis, or transgene expression in the case of vectors, proceeds (41,42).

Once in the nucleus, the E1a gene is the first viral gene that is expressed. Because the E1a products have a key role in controlling viral replication, early transcription and DNA synthesis, the earliest adenoviral vectors had deletions in their E1 region (43). Premature cell death is regulated by the expression of E1b products, E1B-19K. Furthermore, E1 proteins protect the infected cell from the action of interferons  $\alpha$  and  $\beta$ . The E3 gene products are also important in preventing an immune response; they serve to protect infected cells by preventing cytolysis by cytotoxic T lymphocytes (CTLs) or tumor necrosis factor  $\alpha$ . Cells expressing the E3gp-19K are protected from CTLs because the protein binds directly to the peptide-binding domain of MHC I, causing its retention and thereby preventing presentation of viral antigen by infected cells.

Following the onset of DNA replication, the major late promoter becomes active, enabling transcription of the late genes, which produce the capsid and internal structural proteins. The capsid proteins are then transported from the cytoplasm to the nucleus, initiating viral assembly. Ad genomes of the correct size together with

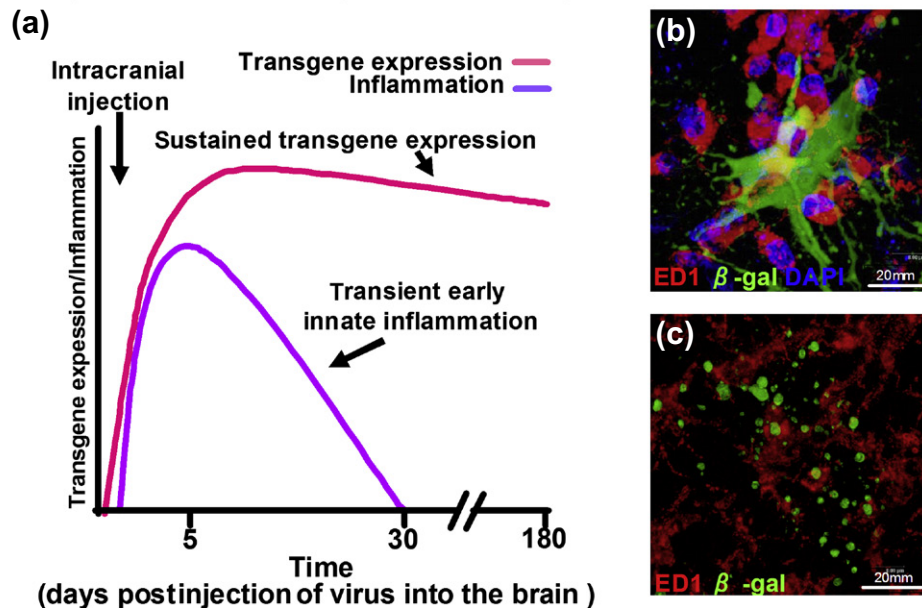

an appropriate packaging signal are packaged into virions. The Ad life cycle is terminated by cell lysis, and the release of 10,000 viral particles per cell (44).

**29.2.3.1 First-Generation AdV.** The most common first-generation AdVs developed for gene therapy are based on the Ad2 and Ad5 serotypes, since the genetics and biology of these viruses had been extensively investigated. Initial recombinant AdVs were made replication defective through deletions in the E1 region, where the transcriptional cassette could be inserted; most also contained small deletions in E3 to increase cloning capacity. A human embryonic kidney-derived 293 cell line was used to provide the E1A and E1B functions in trans. Recombinant AdV expressing a transgene of interest could then be generated by homologous recombination between the backbone of the virus genome and a shuttle plasmid containing the expression cassette flanked by a region of viral DNA. As a result, 90% of the wild-type Ad genome is retained in these first-generation vectors (45).

First-generation E1-deleted AdVs have a number of positive characteristics. One of the most important is their relative ease for scale-up of titers reaching above 1012 IU/mL (infectious units/milliliter). Other attractive features include the ability to infect many different cell types, both dividing and non-dividing, and having an extremely low probability of random integration into the host chromosomes (46). The majority of first-generation AdVs are also deleted for the E3 region, which is not required for virus replication in cell culture. E1, E3-deleted Ad vectors theoretically allow for DNA insertion of around 8 kb.

First-generation AdVs have been used to successfully deliver genes to a wide variety of tissues and organs in animal models of human disease and in the majority of the more than 400 human Phase I clinical trials worldwide using adenoviral vectors. In general, Ad-mediated gene therapies have been well tolerated, with only minor, transient side effects (47–49). In spite of the early region deletions, first-generation AdVs have residual expression of viral genes that lead to a strong host-adaptive immune response, resulting in generation of high titer neutralizing anticapsid antibodies that inhibit reinfection with the same serotype of AdV (50), as well as a CTL response directed against various proteins expressed from the wild-type genome sequences. After systemic delivery of vector, the Ad capsid proteins appear to immediately activate chemokine expression from infected cells, commonly referred to as the innate immune response (51). In addition, at high viral doses this residual virus gene expression leads to cellular cytotoxicity, which can result in an immune-mediated loss of the transduced cells (52). Although injection of first-generation recombinant AdV into the brain parenchyma causes acute cellular- and cytokine-mediated inflammatory responses, this does not affect transgene expression. In the presence of adenoviral immune responses, transgene expression for

### Adenovirus-mediated acute inflammation is transient and does not affect transgene expression long-term from first-generation or HC-Adv vectors

**FIGURE 29-5** (a) Schematic illustration of the time course of the acute adenovirus-mediated innate inflammatory response. (b, c) Innate immune responses in the brain in vivo. Injection of  $1 \times 10^8$  i.u. of RAd36 into the rat brain. (b) Macrophages/microglia immunoreactive for ED1 (in red) contact  $\beta$ -gal expressing cells (green). (c) Presence of  $\beta$ -gal immunoreactivity within macrophages, indicating that ED1-immunoreactive brain macrophages/microglia have phagocytosed dead transduced brain cells.

first-generation adenovirus is rapidly ablated (53,54). Adenovirus-induced cytotoxicity is only seen when high vector doses of  $>10^8$  i.u. are used to transduce the target tissue (55) (Figures 29-5 and 29-6).

**29.2.3.2 Second-Generation AdVs.** To overcome the immunological problems caused by proteins expressed from the wild-type sequences in adenoviral vector genomes, a series of Ad vectors with further deletions were developed. In order to propagate multiple deleted Ad vectors packaging cell lines were developed that trans-complement the growth and packaging of these vectors. To date, packaging cell lines coexpressing the Ad E1 and E4 genes, the E1 and E2a (single-strand DNA-binding protein, ssDBP) genes, the E1 and preterminal protein genes, and the E1 and protease genes have been generated and used to package the E1, E4-deleted Ad vectors (56), the E1, E2a-deleted Ad vectors (57), the E1, E2b-deleted Ad vectors (58), and the E1- and protease-deleted Ad vectors (59), respectively.

**29.2.3.3 E1,E4-Deleted AdVs.** The E4 region is located at the right end of the Ad genome and encodes seven open reading frames. The E4 protein has several functions, including regulation of Ad replication and late gene expression (60). Upon administration of the E1,E4-deleted Ad vectors, the transgene expression was extremely transient, likely due to the lack of an E4-encoded trans-acting factor that can influence expression from some promoters (61). Comparing the toxicity with first-generation Ad vectors, E1,E4-deleted Ad vectors demonstrated prolonged transgene expression and

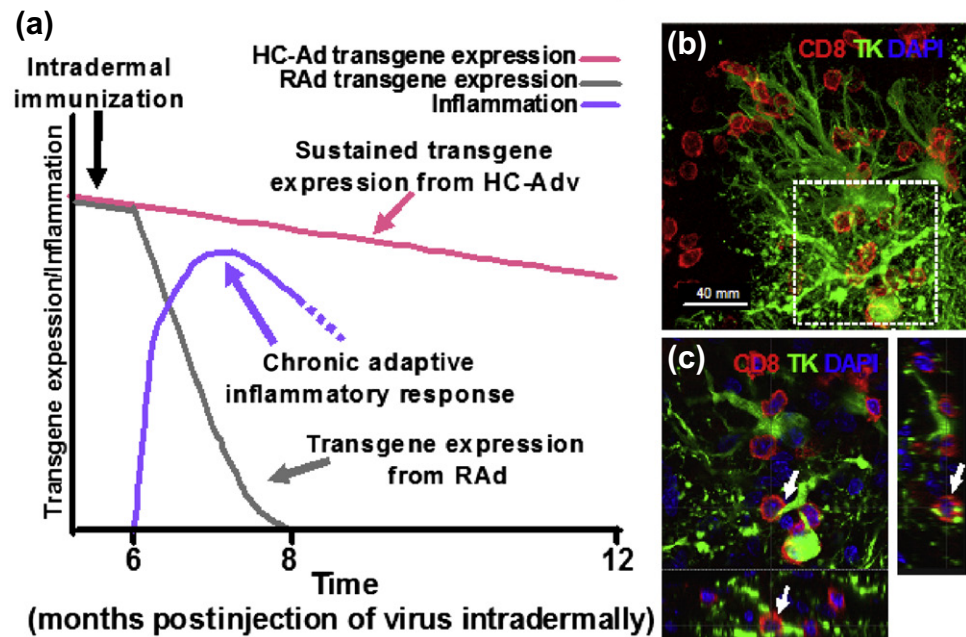

decreased evidence of hepatotoxicity (62). The cloning capacity of this vector is up to 10 kb.

**29.2.3.4 E1,E2a- or E1,E2b-Deleted AdVs.** The E2 region can be subdivided into E2a and E2b. E2a encodes a 72-kDa DBP that is essential for the initiation of viral DNA synthesis and for the activation of the major late gene expression. E2b encodes a 140-kDa DNA polymerase and an 80-kDa precursor terminal protein, both of which are required for viral DNA replication. Intravenous infusion of an E1,E2a-deleted AdV encoding human factor VIII into primates resulted in physiological plasma levels of hFVIII, facilitated by widespread hepatic transduction (57). E1,E2a-deleted Ad vectors have shown improved decreases in inflammatory responses but are difficult to grow at high titers. Recently, an E1,E2a-deleted AdV has been utilized as helper virus for propagation of helper-dependent AdVs (discussed below) in order to further minimize any toxicity that may be attributable to helper virus contamination (63). The main advantages of E1,E2b-deleted AdVs are reduced acute toxicity, extended persistence of the transgene, and ease of scale-up.

**29.2.3.5 100K, Protease-Deleted AdVs.** The 100K gene and protease functions are normally expressed only after Ad replication occurs. The 100K protein is necessary for Ad capsid assembly, hexon monomer protein transport from the cytoplasm into the nucleus and hexon trimerization. The protease is required for full maturation of the capsid. AdVs deleted for 100K or protease are not affected in their ability to replicate their genomes,

### Systemic immunization against adenovirus eliminates transgene expression from first-generation adenovirus and causes prolonged brain inflammation, but does not abolish expression from HC-Adv

**FIGURE 29-6** Careful injections of vectors into the brain parenchyma, in the absence of systemic delivery of vector antigens, lead to long-term expression; (a) the time course of the adaptive adenovirus-mediated immune response that occurs following a systemic priming of the immune system. (b, c) Adaptive immune responses in the brain in vivo. Presence of CD8<sup>+</sup> T cells within the brain parenchyma of a systemically immunized rat, following the injection into the brain of RAAd-TK. In (a) we illustrate triple labeling with CD8 (red), thymidine-kinase-positive cells (green) and nuclei (DAPI, blue). Note the presence of CD8-positive cells in the striatum of a rat injected intracranially with RAAdTK and immunized intradermally with RAAdHPRT, and killed 14 days after the immunization. CD8 cells usually were close to TK-positive brain cells (a). We could detect frequent contacts between CD8 cells and TK-positive cells (c, arrows). The analysis of the contacts can be observed in 0.5- $\mu$ m-thick optical layers examined by confocal microscopy, illustrated by the views from the x- and y-axes as shown in (b). Notice that whereas activation of the innate immune response does not eliminate transgene expression the adaptive immune response does. The mechanisms by which the adaptive immune response achieves this remain to be demonstrated.

but packaging of the replicated vector genomes is abolished. The 100K or protease-deleted AdVs enable higher transgene expression levels at much lower dosages of vector, resulting in decreased toxicity (59,64).

**29.2.3.6 Helper-Dependent Adenoviral Vectors.** In spite of statistical improvements to toxicity and longevity of expression with second/third-generation adenoviral vectors, immune responses were not abolished and toxicity from remaining wild-type sequences could not be eliminated. Thus, Frank Graham and collaborators aimed to eliminate completely all vector-encoding sequences from adenoviruses vectors. A number of strategies were initially shown to be possible. The biggest challenge was to eliminate any first-generation vector used as a helper virus from the final vector preparations. Eventually, the strategy based on the removal of the packaging signal from the helper first generation through recombinase-mediated removal, turned out to be the most efficient. Similarly, this strategy is also the most effective in generating completely deleted amplicon HSV1 vectors.

Helper-dependent adenoviral vectors (also known as high-capacity “gutless” vectors (HD-Ad)) have been developed that are devoid of all viral coding sequences

(65–68). These vectors have a minimum requirement for the ITR of the linear adenovirus genome, containing the cis-acting elements for viral DNA replication and packaging, and the packaging signal. Since these elements are contained approximately 500 bp from the ends of the genome (69), helper-dependent vectors have the potential to range in size from a few hundred base pairs to carry up to approximately 36kb of the foreign DNA, which is close to the size of the native Ad genome. HD-Ads are copropagated with an E1-deleted helper virus, which provides in trans all proteins required for the propagation of the vector.

Several systems have been developed to prevent packaging of the helper viral genomes during the HD-Ad vector rescue/amplification process in order to minimize the helper virus contamination. The Cre/loxP-based system for the generation of HD-Ad involves the use of a first-generation helper virus where the packaging signal is flanked by loxP recognition sites (70). Infection of Cre-expressing 293 cells with the helper virus results in excision of the viral packaging signal, rendering the helper virus DNA unpackageable but still able to replicate and provide helper functions for HD-Ad vector propagation (71). Purification by cesium chloride centrifugation is

necessary to reduce the titer of the helper virus to negligible levels, typically ranging from 0.1% to 0.01% of the HD-Ad vector titer. Recently, another Flp/rtt-based system has been developed. The Flp recombinase was used in place of Cre and has shown to excise the rtt-flanked packaging signal in helper virus efficiently (72,73). The recent improvement to this system is the development of a new Cre-expressing cell line based on E2T, an E1 and E2a complementary cell line. Thus, an E1 and E2a double-deleted helper virus can be used with the new cell line to produce HD-Ad vector with low helper contamination and further improving the HD vector safety (63). Another major obstacle currently hindering the progress of HD vectors is the difficulty of large-scale vector production. Recently an improved producer cell line was generated along with protocols that have successfully addressed common problems. With this system,  $>1 \times 10^{13}$  viral particles can be easily produced from 3L of cells within 2 weeks of vector rescue, with specific yields of  $>10,000$  vp/cell and with exceedingly low helper virus contamination of 0.4%–0.1%. This new system represents a major improvement over the original method in terms of simplicity, speed, vector yield, and purity and it will significantly improve our ability to assess this promising gene therapy technology, especially in large animal models and ultimately for clinical applications (74).

Owing to the large cloning capacity of HD-Ad vectors, there is enough cloning space to contain large regulatory regions or to produce hybrid vectors that combine the advantage of a two-vector system. Regulatory gene expression by HD-Ad vectors can be achieved by using a tissue-specific promoter, so that the transgene is only expressed in a specific organ or tissue (75). Another option for regulating gene expression is to use a promoter that is only active after addition of an exogenous compound (76). This regulatable HD-Ad vector system represents an important tool for transgene regulation that can be used for potentially diverse applications, ranging from tissue-specific gene expression in transgenic animals to human gene therapy.

Compared with first-generation AdVs, the HD-Ad vector can also efficiently transduce a wide variety of cell types from numerous species in a cell-cycle-independent manner. The HD-Ad vectors have the added advantage of increased cloning capacity, reduced toxicity and immune responses and prolonged stable transgene expression *in vivo* (55,77–80). The limitations of HD-Ad vectors consist of difficulties in large-scale production and helper virus contamination. If these shortcomings can be overcome by improved viral vector production technique, then the HD-Ad vector will become one of the key viral vectors for gene therapy. To date, no peer-reviewed publication reports their use in human clinical trials, although one such trial has apparently been conducted.

As with other vectors discussed, replication-competent adenoviruses are also being developed for the clinic.

The first oncolytic virus to be used in human trials was Onxx-015, an E1B 55-kDa gene-deleted adenovirus that is expected to replicate in and lyse cells that are deficient in the tumor suppressor gene p53. This vector appears to be more effective in combination with chemotherapy (81). The utility of replication-competent oncolytic adenoviruses against cancer has been recently reviewed (82).

### 29.2.4 Adeno-Associated Vectors

Adeno-associated virus (AAV) is a small human parvovirus having a 4.7kb linear single-stranded DNA genome. It has not been associated with any human disease and its genome is integrated in a site-specific manner, thereby allowing stable transgene expression without the risk of mutation caused by random integration, which makes this virus a good candidate for a gene therapy vector (12). AAVs are capable of infecting a wide variety of hosts but this usually depends on coinfection with a helper virus (either adenovirus (Ad) or HSV) for a productive infection (83). A total of 11 different serotypes have been cloned (84,85). Most studies to date have focused on AAV-2 and AAV-5. Serotype 2 of AAV (AAV2) was cloned first and is most commonly used to derive vectors. Various regions of the brain have successfully been transduced by rAAV vectors (86–89), with apparently no toxicity. In the striatum, rAAV2-mediated gene expression under the control of the cytomegalovirus (CMV) promoter was shown to be maintained up to 1 year (89,90). Little is known about the mechanism underlying the stability of rAAV2-mediated gene expression in the brain.

The AAV genome is composed of two open reading frames called rep and cap, which are bounded on either side by ITRs. The ITRs contain the viral origins of replication and are the only cis-acting elements, which are required for efficient encapsidation and participate in viral DNA integration (91). The rep region encodes for proteins, which mediate AAV replication, viral DNA transcription and endonuclease functions used in host genome integration. The rep genes are the only AAV genes that are required for viral replication. The cap sequences encode structural proteins that form the viral capsid.

All vectors are derived from a plasmid, which retains only the AAV 145-bp ITRs flanking the transgene cassette of choice. The deleted viral coding sequences are present on a separate template, referred to as an AAV helper or packaging plasmid. The current method used to generate defective AAV vectors takes advantage of the fact that the ITRs are the only cis-acting elements required in a plasmid vector for rescue, replication and packaging. All other elements, including the rep/cap gene products and helper virus proteins (Ad E1a, E1b, E2a, E4 and VA), can be supplied *in trans* by co-transfecting the plasmids simultaneously in the human embryonic 293 cell line (91). This three-component plasmid results

in the generation of mixed stocks of rAAV and Ad. Stable rAAV is usually purified by inactivating the contaminating Ad by heating at 56°C for 45 minutes followed by CsCl centrifugation. This allows rAAV to be purified to titers between  $10^7$  and  $10^{10}$ . This production of large-scale viral vectors is labor intensive. Recently, the development of better packaging cell lines and column chromatographic methods of vector purification have improved the rescue method (92).

Generation of rAAV requires transfection of the vector and packaging constructs into Ad-infected cells. Owing to the lack of homology between vector and helper sequences, rAAV produced in this system is essentially free of wild-type AAV; however, the primary concern is the need to remove the contaminating Ad particles. In addition, the inherent competition between AAV and Ad for critical viral gene functions affects the final yield of vectors generated. Complete removal of Ad has relied on physical techniques such as CsCl<sub>2</sub> gradients, column chromatography and a heat-denaturing step to inactivate any residual Ad particles that may still be present. Although most of these procedures have succeeded to various degrees, the potential for Ad contamination is an unwanted risk and the presence of Ad denatured proteins is unacceptable for clinical use (93). Recent improvements have eliminated the need for Ad helper virus. In this system the Ad helper functions are delivered from a plasmid, pXX6, which contains the essential helper genes but lacks the Ad structural and replication genes. Furthermore, combination of these two new plasmids increases rAAV vector yields by 40-fold and also increases the infectivity and transduction compared to conventional procedures that use Ad particles as the helper (94).

The advantages of rAAV are that (1) it is an integrating vector, with the potential of persistent transgene expression following integration, (2) it efficiently transduces a wide range of host cells, and most importantly, (3) wtAAV is nonpathogenic. Initial experiments investigating the immune response against rAAV vectors in the muscle of mice showed only mild and transient inflammation. However, neutralizing antibodies were generated and could significantly reduce the efficacy of vector readministration (95). Other studies have looked at the CTL and antigen-presenting cell (APC) responses to rAAV vectors. rAAV delivery to mouse muscle showed the development of high titers of neutralizing antibodies, and no cell-mediated immune responses were detected. The observation that APCs present in some tissue, such as muscle, are not efficiently transduced by rAAV, do not express transgene products and do not proliferate may explain the lack of cellular immune responses (96,97). This view is controversial, however, and it has been shown that CTL and humoral responses to a delivered transgene depend on a number of variables. These variables include the nature of the transgene, route and site of injection, the immunological background of the recipient, the degree of

contamination with helper virus and the maturation state of APCs exposed to rAAV administration (98).

The main drawbacks of rAAV are (1) limited cloning capacity (4.5 kb) available for the transgene, (2) difficulty producing high titers, (3) presence of helper virus in purified stocks and (4) the fact that total elimination of the helper virus may modify some AAV properties, such as the infection of nondividing cells or integration into the host genome. Several strategies are being explored to expand the cloning capacity of rAAV, including the development of hybrid viral capsid structures, the use of very small promoters and heterodimerization of separate rAAV vectors. So far these manipulations have resulted in the doubling of the cloning capacity of rAAV (99,100).

Overall, rAAV, which is a relatively new vector for gene therapy, appears to be a promising tool for the future. These vectors are able to transduce a large variety of cells, including non-dividing cells, and they are associated with minimal toxicity, thereby providing a high degree of safety. The vector has been successfully delivered *in vivo* to many different organs (for example, CNS, liver, lung and muscle). Moreover, there have been reports of preclinical efficacy in different animal models of genetic and acquired diseases. Clinical trials using rAAV for the treatment of cystic fibrosis are underway with early evidence of gene transfer and expression of the human clotting factor IX in haemophilia B patients (12).

It has been reported that AAV vectors enter the cell rapidly but uncoat very slowly. This was found to be especially the case for AAV2 vectors, which can uncoat over approximately 8 weeks. This has particular immune consequences. Although AAV2 vector genomes do not express any viral capsid proteins, the slow uncoating would make viral capsid proteins available to the immune system over a very long time, potentially long enough to either prime the immune system or to make available antigenic epitopes over the time it takes the vector to uncoat. This slow uncoating is thought to explain, at least in part, the slow increase in AAV-mediated expression, as well as some untoward immune responses. Interestingly, other AAV serotypes, such as AAV1, 6, and 8 uncoat much faster than AAV2 and also have individual patterns of tissue distribution, cell-type-specific transgene expression and immune responses, which are currently being examined in detail. With particular reference to gene therapy for the brain, AAV9 has recently been reported to have an unusual ability to cross the blood–brain barrier and thus transduce cells of the CNS after intravenous administration (101).

## 29.2.5 Other Vectors

**29.2.5.1 Measles Virus.** Six Phase I clinical trials have been completed or are under way using vectors derived from the enveloped, single-stranded negative-sense RNA paramyxovirus that causes measles. Five are anticancer treatments and one is an HIV vaccine trial. Results have

been reported for a clinical trial using a measles-derived vector to treat ovarian cancer (102), and preclinical studies leading to the first clinical trial of a measles virus-derived vector for glioblastoma have been described (103).

**29.2.5.2 Newcastle Disease Virus.** Another member of the Paramixoviridae that shows promise as an oncolytic virus is the causative agent of Newcastle disease. While extremely dangerous for birds, particularly domestic poultry, this virus poses little danger to humans but appears to proliferate preferentially in tumor cells (104). It was administered therapeutically to cancer patients as early as 1999 (105), and a Phase I/II trial examining the feasibility of treating glioblastoma with Newcastle disease virus has been completed in Israel (106).

**29.2.5.3 SV40.** Louboutin et al. (107) report that a vector derived from the simian polyoma virus SV40, deleted for the oncogenic large T antigen, could be injected intravenously in mice and transduce large numbers of mature neurons, particularly if mannitol administration was used to increase blood–brain barrier permeability.

## 29.3 DEVELOPING CELL-TYPE-SPECIFIC AND REGULATABLE GENE DELIVERY VECTORS

Gene therapy is emerging as an effective tool and will soon be a major consideration in therapeutic medicine. The next challenge for the field is to develop techniques that will target the therapeutic gene specifically to the damaged or “sick” tissue and to have control of when the gene is turned on and off. Developments in gene regulatory systems have produced effective regulatory switches to tightly activate and silence therapeutic genes in order to alleviate and control the recurring symptoms of a neurodegenerative disease without causing harmful side effects from constant expression of the transgene. The use of exogenous substances to facilitate the regulatable switch is becoming the preferred method for controlling the presence and absence of the transgene.

For a transcriptional regulatory model to be effective for clinical gene therapy applications, it has to satisfy five criteria. These are (1) zero or negligible basal activity and expression of the therapeutic gene in the absence of the transcriptional inducer, (2) good induction kinetics, (3) high sensitivity to the inducer on administration, (4) tight transgene regulation, and (5) negligible or minimal immune-mediated cytotoxicity or inflammation associated with the transactivator of the regulatory switch system. Consequently, administration of lower inducer concentrations to the patient in the clinical perspective will be safer. In adjunct to levels of therapeutic vector titers and extent of their readministration within the brain, the quantity, concentration and frequency of inducer administration to the patient to attain the required levels of therapeutic product are crucial factors that require careful evaluation in preclinical studies on testing and employing antibiotic-based gene control systems (Table 29-1). A regulatory

switch with substantial promise for somatic gene therapy is the tetracycline (tet)-dependant regulatory system. The system is essentially composed of two types of switches that are categorized as the tet-off and tet-on models. A plethora of literature reviews on these regulatory systems has been published over the years to illustrate their successes in achieving regulated gene therapy (Figure 29-7).

### 29.3.1 Molecular Mechanisms of Tet-On- and Tet-Off-Based Transcriptional Regulatory Systems

The discovery of mammalian regulatory transcriptional expression systems initially arose from experimental research done on the bacteria *Escherichia coli* (108). The use of tet-based inducible switches to regulate transcriptional genes has demonstrated an enormous benefit in physiological and clinical medicine. The tet-on and tet-off regulatory systems have been repeatedly upgraded over the years to achieve enhanced induction kinetics and regulation of gene expression. The core switch of the conventional tet-off system functions with the synchronized interaction of two basic components. These are the tet repressor protein (TetR) and the tetracycline response element (TRE). The TetR was initially discovered in the bacterial strain *E. coli*, in which the TetR negatively regulates genes of the tetracycline-resistance operon on the Tn10 transposon. In bacteria, the TetR hinders transcription of these genes by binding to tet operator sequences (tetO) in the absence of tetracycline. The TetR is a 37-kDa protein made up of 207 amino acids. Fusion of TetR to a viral protein called VP16, a eukaryotic transactivator derived from HSV type I, transforms the TetR from a transcriptional repressor to an activator called transactivator (tTA). The tTA, equipped with its own promoter and poly(A) sequence, is independent of the TRE-driven transgene cassette.

The TRE unit is composed of seven recurring tetO and is situated upstream of the immediate transgene initiation codon sequence of the minimal human CMV (hminCMV) promoter, driving the transgene encoded cassette. Gene regulation is achieved by the synthesis of transactivators and their resulting interaction with the inducer and TRE. In the tet-off system, gene expression is switched “on” and turned “off” in the absence and presence of the inducer (tetracycline or an analog, i.e., doxycycline), respectively. When the gene is switched off upon delivery of doxycycline (dox), dox becomes bound to the constitutively synthesized tTA. The dox-bound tTA hinders the ability of the tTA to become docked to its tetO sequences within the TRE and thereby impedes subsequent gene expression. When the gene is switched on, due to the absence of the dox inducer, the tTA binds freely to its operator sequences (tetO sequences) within the TRE, triggering TRE and its promoter to induce gene expression.

Gossen and Bujard (109) created an altered form of the tTA by mutating the original TetR fused to the

## Turning transgenes (medicines) on and off

**FIGURE 29-7** In vivo transgene expression from HC-Ad-mTetON- $\beta$ -Gal (left-hand panels) in the rat brain, using the Tet-ON system. Rats were injected with  $1 \times 10^7$  blue forming units (BFU) of HC-Ad-mTetON- $\beta$ -Gal and received drinking water with 1% sucrose plus 2.0 mg/mL Dox (DOX +) or drinking water with 1% sucrose alone (DOX-) for 6 days. Transgene expression was determined by  $\beta$ -galactosidase immunocytochemistry. Images show  $\beta$ -Gal-immunopositive cells in striatal sections in the ON condition (Dox+) but not in the off condition (Dox-). In vivo transgene expression from GFAP-Tet-Off- $\beta$ -gal, and NSE-Tet-Off- $\beta$ -gal in the hippocampus of rats is shown in the right-hand figure. This demonstrates the astrocyte specific expression from the GFAP promoter, in the top right panels, and the neuronal specific expression from the NSE promoter in the lower right panels. In red, expression of  $\beta$ -galactosidase was detected by immunocytochemistry, and in green, the expression of the cell type specific markers was assessed (GFAP in the top right panels, and NeuN in the lower right-hand panels). Double labeling renders the appropriate cells yellow indicating that the right cell type expresses the transgene in the ON situation. Because of the use of the Tet-Off system in these experiments, the ON condition is Dox-, whereas gene expression is turned OFF by providing Dox to the animals. This figure illustrates that cell-type-specific and inducible transgene regulation can be achieved both from first-generation adenoviral vectors (right-hand panels), and high-capacity adenoviral vectors (left-hand panels).

VP16 by four amino acid changes within the protein core, where the inducer becomes bound, resulting in the tTA exhibiting reverse functions. This mutant, termed rtTA, triggers transcription in the presence of the inducer instead of repressing transcription in the presence of the inducer, resulting in the development of the tet-on system. This reverse transactivator has been utilized successfully in achieving the desired regulated gene expression in a number of experimental studies but had some limitations in achieving tight gene regulation. Despite the absence of the dox inducer, tet-on-based rtTA was found to exhibit some level of affinity to the tetO that makeup the TRE, thus activating the target promoter and inducing a basal level of transcription in the off state. Urlinger and colleagues (110) induced random and site-directed mutagenesis in rtTA seeking novel forms that can enhance tight regulation and therefore minimizing background expression in the absence of the inducer to negligible levels. Using *Saccharomyces cerevisiae* for screening assays, studies revealed five rtTA mutants, one of which produced negligible basal expression in the absence of the inducer and required a 10-fold-lower doxycycline concentration for TRE activation. This rtTA mutant transactivator was named rtTA2S-M2. Quantitative analysis of luciferase assays with rtTA2S-M2 transactivator revealed tight regulation of  $\beta$ -galactosidase gene expression in transfected HeLa X1/6 cells (110).

Despite extensive characterization in animal models, including non-human primates (111) and dogs (112), no

use of a vector with tetracycline regulatable transgene expression has yet been reported in humans.

### 29.3.2 Latest “Tet-On”-Based Tetracycline-Dependent Transactivators

Tight regulation of therapeutic gene expression is of critical importance when considering implementation of gene therapy to the human trials. Tet-on-based regulatable gene expression systems for clinical gene therapeutics are better than the tet-off system in theory because less antibiotic needs to be used. The tet-off system requires more antibiotic in order to sustain gene expression in the off state. This constant presence of antibiotics in circulation could lead to complications because of a growing resistance to the antibiotic or unwanted side effects. Therefore, novel tet-on transactivators of tetracycline-dependent regulatable systems are more appropriate, as they do not require constant administration of the drug and gene expression is switched on only when needed.

In contrast to the conventional rtTA-based tet-on systems, the latest generated regulatory switch composed of a tetracycline response promoter coengineered with mutant rtTA2SM2 transactivator and a tTSkid repressor, via an internal ribosome entry site (IRES), has recently shown to be effective in producing tight regulation of transgene expression in mice and nonhuman primates (113,114). Lamartina and coworkers developed and tested a bicistronic vector ex vivo containing a single regulatory cassette, encompassing rtTA2S-M2

transactivator and tTS-Kid tet repressor separated via an IRES. The rtTA2S-M2/IRES/tTS-Kid complex produced negligible basal activity, had 1000-fold inducibility of serum alkaline phosphatase gene expression and exhibited elevated sensitivity to doxycycline (113). This novel regulatory switch has the characteristics of an ideal tet-on regulatory model for gene therapy applications.

Applying the tet-on regulatory switch system containing the rtTA2S-M2/IRES/tTS-Kid complex to the HC-AdV provides a strong gene therapeutic tool. This vector will express high levels of the transgene while being tightly regulated to produce the therapeutic gene at specific times and therefore minimize side effects caused by overexpression of the transgene. Excellent disease candidates for which this regulatable switch system can be utilized are neurodegenerative diseases such as Parkinson's disease (PD) that produce recurring symptoms. This disease is a consequence of a defect in the dopaminergic circuit of the basal ganglia that sustains and controls motor activity. It has been shown that using first-generation adenoviral vectors in the 6-OHDA animal model will reduce disease symptoms (115). Using HC-AdVs coengineered with specific neurotropic factors under the control of the rtTA2S-M2/IRES/tTS-Kid tet-on regulatory switch, tight regulation can be achievable, and hopefully similar, if not better, therapeutic results can be achieved compared to the first-generation vectors. This approach can be ideal in the clinical setting for the treatment of PD, since the tet-on transactivator facilitates tight regulation of gene expression with negligible background expression in the uninduced state. Preclinical testing of neurotropic-gene-encoded HC-AdVs coengineered with the regulatory switch will allow us to further improve and examine these gene therapeutic strategies for PD (Table 29-1).

The well-established tetracycline derivative doxycycline, principally due to its nontoxic effects, is a broadly employed antibiotic in treatment medicine. A recent study by Chtarto et al. (116) has discovered an additional tetracycline derivative that was revealed to be effective and less cytotoxic than doxycycline in vivo. Minocycline, an antibiotic that is considered to exhibit antiapoptotic and antiinflammatory properties, exhibited reduced cytotoxicity and a faster elimination time of minocycline withdrawal compared to doxycycline. Although emerging doxycycline-based tet-on regulatory systems show promising results, studies on regulation kinetics are important to further optimize this and other tet-on systems to initiate and promote safe gene therapy treatments in the clinical milieu.

### 29.3.3 Other Transcriptional Gene Regulatory Systems

Before the emergence of the widely employed tetracycline-based regulatory systems over a decade ago, earlier developments on other gene regulatory systems demonstrated both successes and failures in inducing tight

transgene regulation. Initial efforts in constructing these systems relied primarily on the use of endogenous promoters that induce gene expression. Such endogenous promoters included heat shock (117), heavy metals (118), interferons or ds RNA (119), or steroids (120). Some primary drawbacks of these methods included the heavy dependence on endogenous transcription factors and second, complications in generating consistent in vivo results comparable to results from in vitro studies.

Although the bacterial lac operator–repressor system does not function in vivo, the lac system has shown successful gene regulation in vitro. It produces minimal levels of basal activity and high induction levels of the transgene in the presence of the inducer isopropyl- $\beta$ -D-thiogalactoside (121). In contrast to the lac system, the RU 486 regulatory system produced successful tightly regulated transgene gene expression both in vivo and in vitro. This system fundamentally operates on the progesterone regulatory system that is dependent on the inducer RU 486 to regulate transcription of genes (122). Other notable regulatory systems developed that generated efficient and tight regulation of gene expression both in vivo and in vitro were the *Drosophila melanogaster* receptor-hormone-dependent ecdysone system (123) and the rapamycin system based on the human FK506-binding protein/FKBP12-rapamycin associated protein (FKBP/FRAP) protein interaction (124).

### 29.3.4 Cell-Type-Specific and Regulated Gene Expression in the CNS

In addition to the therapeutic-gene- and regulatory-switch-encoded viral vector for gene transfer, a fundamental element needed to achieve localized transgene expression within specific cell types is the use of a specific promoter driving expression of the therapeutic transgene within localized cells. Excellent examples of such cell-type-specific targeted gene therapy have been demonstrated in animal models with induced pituitary tumors, illustrating the feasibility and effectiveness of this approach (95, 125–127). With the application of cell type specificity and regulatory switches coengineered within the adenoviral vector and direct stereotactic injection of adenoviral vectors to the affected brain anatomy in animal studies, gene therapy has become a more powerful approach for the treatment of neurological diseases. Smith-Arica et al. (95) have demonstrated that effective antibiotic-based transcriptional gene regulation and cell-type-specific transcriptional targeting produced successful regulatable transgenes in experimental cell lines and targeted localized regions within the rat brain. A first-generation adenoviral vector encoded with a glial fibrillary acidic protein (GFAP) promoter, which drives the expression of GFAP under the control of the tet-off regulatory switch, produced localized doxycycline-dependent GFAP expression within glial cells in vitro and in vivo in a dose-dependent manner.

The use of a neuronal-specific enolase (NSE) promoter to induce expression within neurons in the absence of doxycycline, however, did not exhibit neuronal-restricted transgene expression in cell lines *in vitro* but produced successful transgene specificity *in vivo* (95). Taking into perspective the results of these studies, the choice of a specific promoter does not always produce the expected localized transgene expression. For the development of human neurological gene therapy, careful testing of the promoter through experimental studies will allow us to verify its specificity *in vitro* and *in vivo*. In a comparable study by the same group, specific promoters restricted to the anterior pituitary-hormone-synthesizing cells in a first-generation adenoviral vector encoded with the tet-off tetracycline-responsive transcriptional cassette expressed the predicted regulatable transgenes within targeted cell populations in both *in vitro* and *in vivo* studies (95).

Compared to the strong  $\beta$ -actin/human nonspecific (CAG) promoter, using first-generation recombinant adenoviral vectors engineered with TRE and the human prolactin promoter led to transgene expression only within GH3 tumor and lactotrophic cells (125). A fundamental idea to be learned from *in vivo* and *in vitro* studies is that a conscientious choice of promoter is crucial for achieving and maintaining appropriate transgene expression.

A promising advance in cell-type-specific control of transgene expression has been the recent development of microRNA-regulated systems (128). These systems exploit the ability of microRNAs—small non-coding RNA sequences—to interfere with the translation of mRNA containing sequences of partial complementarity to the microRNA in their 3' UTR. The endogenous regulatory microRNAs are expressed in a cell-type-specific pattern, and if the cell type of interest expresses a microRNA with a known target sequence, this sequence can be included in the 3' UTR of the transgene. An interesting application of this technology was described by Gentner et al. (129) for the gene therapy of globoid cell leukodystrophy. This disease is caused by defective production of the enzyme galactocerebrosidase (GALC) and can be corrected by transfer of hematopoietic stem cells expressing the wild-type protein. Among the cell types that develop from these stem cells are microglia that migrate into the brain and, if sufficient enzyme is secreted, they can compensate for the lack of endogenous expression. The level of expression that is required from the differentiated microglia is toxic to the stem cells in their predifferentiation stage, precluding the use of a simple strong promoter. To overcome this problem, Gentner et al. included the target sequence for microRNA-126 in the GALC-encoding vector with which the hematopoietic stem cells were transduced. This microRNA is expressed in the stem cells and suppresses expression of the transgene but then is downregulated in the differentiated progeny, allowing robust transgene expression.

## 29.4 THE CLINICAL SCIENCE: TOWARD GENE THERAPY OF HUMAN DISEASE

### 29.4.1 The Beginnings of Clinical Use of Gene Transfer and Gene Therapy

The first vectors that were tested in human patients were actually used in a trial of cell marking, rather than treatment of disease, by the team of Malcolm Brenner at St. Jude Children's Research Hospital in Memphis. At that time an important question was whether relapses following stem cell rescue as therapy for malignant disease were due to insufficient killing of tumor cells remaining in the patients or due to tumor cells remaining in the transplanted bone marrow. This was an ideal question to be answered with the new tools of gene therapy. The question was whether malignant cells at the time of relapse originated from residual malignant cells in autologous marrow. The trials involved transducing bone marrow *in vitro* and reinfusion of marked cells into patients. These studies demonstrated that relapse in acute myeloblastic leukemia and neuroblastoma patients subjected to high-dose chemotherapy and stem cell rescue were due to tumor cells remaining in the infused bone marrow.

The first officially sanctioned and reviewed clinical gene therapy trial for the treatment of disease was conducted by Michael Blaese, W. French Anderson, Kenneth Culver, and colleagues at the Blood and Heart Institute at the National Institutes of Health in Bethesda. Two girls suffering from severe combined immunodeficiency (SCID) due to adenosine deaminase (ADA) deficiency were treated. Their T cells were collected, transduced with an ADA-encoding retroviral vector *in vitro*, expanded and reinfused. Indices of both humoral and cellular immunity showed a tendency to correction, and the two girls have been able to continue with a normal life. These patients continued to be treated, as before gene therapy, with PEG-ADA. The seriousness of the disease, and the fact that it affects children, has impeded the removal of systemically administered PEG-ADA. Removal of PEG-ADA would be the final test to demonstrate the clinical effectiveness of gene therapy beyond reasonable doubt. A subsequent trial in Italy using retroviral transduction of CD34+ hematopoietic stem cells, rather than peripheral T cells, and mild conditioning of the bone marrow with busulfan treatment, has yielded more unconditionally positive results (130). After 2–8 years of follow-up, patients' peripheral blood contained large numbers of various cell types expressing the transgene, numerous immunological parameters were improved, and eight of 10 patients treated no longer required enzyme replacement therapy. Similar successes have been reported from a trial in England (131) for ADA-SCID and also from a trial in France of gene therapy for X-linked SCID (132).

Other notable successes of gene therapy include treatments for X-linked adrenoleukodystrophy (X-ALD) and for Leber's congenital amaurosis. X-ALD is a monogenic

disease cause by mutations in the *ABCD1* gene encoding a peroxisomal membrane transporter protein called ALDP. The disorder is manifested as a devastating progressive demyelination of the CNS, and, as described above for globoid cell leukodystrophy, it can be treated by hematopoietic stem cell transfer because cells expressing the wild-type protein traffic into the CNS and compensate for the endogenous defect. A group in France (133) has reported treating the disease in two patients by transducing autologous CD34<sup>+</sup> cells with a replication-defective, self-inactivated, VSV-pseudotyped lentiviral vector encoding wild-type *ABCD1* and then reinfusing the cells into the patients. Patients' bone marrow was myeloablated to encourage engraftment of the transduced cells. Over 24–30 months of follow-up, cells of several lymphoid and myeloid lineages expressing the transgene were detected in the periphery, confirming successful engraftment, and 14–16 months after treatment, progressive demyelination was halted.

Leber's congenital amaurosis is a group of congenital retinal disorders of which the cause may be a mutation in one of a number of genes. One comparatively common mutation is in *RPE65*, which encodes a protein necessary for retinal pigment epithelium function. Maguire et al. (134) treated three patients with severe and worsening vision loss due to *RPE65* mutations by injecting subretinally an AAV vector encoding human wild-type *RPE65*. Patients were injected unilaterally in their least functional eye, and within 1–4 months of the injection, visual function in this eye was substantially improved. Improvements were reported to be stable without additional adverse events at follow-up more than a year later (135). The basic idea of gene therapy was initially targeted to the treatment of inherited genetic disease, in which inheritance was either recessive or dominant. The very first trials in gene therapy thus addressed the treatment of mostly children suffering from inherited diseases. Once the potential broader applicability of the “genes as medicines” concept was visualized, gene therapy was quickly diversified to be applied to other non-inherited diseases, such as neurodegenerative disorders, cancer and others. Below, we will examine the utilization of gene therapies for the treatment of both inherited and sporadic degenerative disorders and tumors, focusing on the brain as the main target for these new treatments.

## 29.4.2 Applications to Neurodegenerative Disorders

Neurodegenerative disorders are progressive brain diseases, each targeting specific regions of the brain. The diagnoses of the neurodegenerations characteristic of Alzheimer's disease (AD), PD or Huntington's disease are based on clinical, laboratory, genetic and neuro-radiological criteria. AD cell loss targets the neocortex and hippocampus; in Parkinson's, it affects mostly the basal ganglia; and in Huntington's, the basal ganglia

and neocortex undergo progressive massive degenerative changes.

Treatments are symptomatic and vary in their clinical efficiency. Although no treatment delays the progressive nature of brain degeneration, PD symptoms can be treated for many years and the recent use of ACHE inhibitors in AD has somewhat delayed serious memory loss. No treatment has shown any efficacy in Huntington's disease. It is thought that new treatment strategies including gene- and cell-based therapies for the transduction of growth factors and modulation of the immune system offer new opportunities to prevent further neuronal loss.

In addition, transplantation of neuronal precursors has now been tested in two double-blind controlled clinical trials. In spite of some positive effects in some patients, in both clinical trials approximately 15% of patients developed significant side effects that had not been identified in the previous uncontrolled trials from which the results were more promising. As a result of the undesirable side effects, the limited therapeutic effects and the development of other more effective methods such as deep brain stimulation, the upshot of the controlled clinical trials has been reduced enthusiasm for the transplantation of neuronal precursors (Brundin et al. (136)), although many involved with the uncontrolled trials both in the United States and Europe have suggested that they would continue implementing this strategy in human patients. As an alternative, it has been proposed to replace the transplantation of neural progenitors with neural stem cells. This does not solve the issue of how to direct the differentiation of stem cells down the pathway required (137) and to avoid the formations of teratomas. The use of induced pluripotent stem cells derived from patients' own somatic cells also holds great promise (138), particularly since it would obviate the problem of immune-mediated rejection of grafted stem cells, which is currently thought to be a major problem for stem cell transplant therapy (136). It may be more likely in the future to combine stem cells with gene transfer methods; by expressing the necessary transcription factors, gene therapy tools will be able to direct stem cell differentiation in the desired direction in a specific, controllable, and clinically tested manner (139,140). For example Sanchez-Danes et al. (141) report that transduction of human embryonic or induced pluripotent stem cells with a lentiviral vector encoding the ventral midbrain-specifying transcription factor increased the efficiency with which these cells developed the phenotype of ventral midbrain dopaminergic neurons.

**29.4.2.1 Alzheimer's Disease.** AD is characterized by the deposition of extracellular amyloid plaques, intracellular neurofibrillary tangles, synaptic loss and neurodegeneration. Amyloid plaques are composed of insoluble amyloid-beta (A $\beta$ ) fibril fragments of the high-molecular-weight amyloid precursor protein (APP). In familial AD, mutations in presenilin and APP alter the

proteolytic cleavage of APP by secretases, leading to an extracellular accumulation of amyloid plaques. Neurofibrillary tangles are composed of insoluble hyperphosphorylated tau. Normally, phosphorylated tau stabilizes neuronal microtubules. Tangles are thought to lead to neuronal dysfunction, neuronal loss and synaptic loss. These neurodegenerative changes lead to a disruption of the connectivity among various brain regions (142).

Nevertheless, there is still discussion on whether the extracellular amyloid plaques or the intracellular tau neurofibrillary tangles are the primary lesion leading to the symptomatology of AD. Apart from mutations in APP, proteins related to APP processing, and tau, apolipoprotein E (apoE) alleles have been shown to be a risk factor for AD. The apoE4 allele increases, whereas the apoE2 allele decreases the risk of developing AD. The apoE4 allele increases the accumulation of A $\beta$ 42 and its binding properties to tau and decreases the age of onset in a dose-dependent manner (143). Although the noradrenergic and cholinergic innervation of the neocortex is also compromised, it is unclear whether these changes are primary or secondary, and they have not been linked to specific mutations. Given the partial and limited efficiency of AChE inhibitor, it has been proposed that cholinergic neurons arising in the nucleus basalis Meynert and innervating the hippocampus and neocortex may play a central role in disease pathogenesis (144,145).

NGF promotes survival of basal forebrain cholinergic neurons (146). This has led to the use of NGF to attempt to rescue degenerating basal forebrain cholinergic neurons (147–149); however, the causes for the decrease in markers of cholinergic function remain unknown. Cholinergic dysfunction could be a primary defect, or they could be secondary to neocortical degeneration. Understanding the disease pathophysiology will be important in determining the potential therapeutic benefit of cholinergic drugs in AD.

Infusion of NGF into the ventricles of patients with AD had serious side effects such as pain and weight loss (150). As an alternative delivery, transplantation of primary rat fibroblasts producing human NGF were first investigated in fimbria-fornix-lesioned rats (147). After safety and feasibility had been confirmed in primates (151–153), a Phase-I trial was initiated (153).

Eight patients with mild AD showed no adverse effects 22 months after transplantation of autologous fibroblasts obtained from skin biopsies infected with an NGF-expressing MoMLV-derived retroviral vector and stereotactically implanted unilaterally ( $n=2$ ) or bilaterally ( $n=6$ ) into the nucleus basalis of Meynert. Clinical follow-up indicated an apparent slowing in the rate of cognitive decline, and 18F-FDG PET performed in four patients showed a significant increase in cortical glucose consumption after treatment. Developing this paradigm, Ceregene has completed a Phase I/II trial and is currently conducting Phase II clinical trials of CERE-110,

an AAV-derived vector encoding NGF, which is injected into the basal forebrain. The current perspective on this vector is discussed by Mandel (154).

Other gene therapy strategies for AD include transduction of apoE2 (155) to reduce the A $\beta$  burden and the subsequent development of neuritic plaques in AD mice. Most recently there has been much work on immunization approaches to reduce intraparenchymal levels of A $\beta$ . Vaccination with a plasmid that encodes A $\beta$ 42 (156) or by intranasal administration of replication-incompetent AdV carrying both A $\beta$  and GM-CSF genes (157) have been tested. These alternative immunization strategies are currently being developed, as the active immunization with synthetic A $\beta$ 1–42 has been shown to be effective in mouse models to significantly reduce the A $\beta$  burden accompanied by improved cognitive performance, but clinical trials had to be stopped after enrollment of about 300 patients because of the development of a T-cell-mediated aseptic meningoencephalitis in 6% of treated patients (158,159). The interpretation of the results is complicated by the fact that only very few brains were available for pathological analysis. Those that were published indicated that inflammation correlated with reduced plaque load. In the absence of larger samples, it remains difficult to know whether these anecdotal data are significant.

Immunization techniques are clearly double-edged swords. In the trials that proceeded, patients were immunized with endogenous brain proteins. Immunization against brain proteins is known to lead to brain autoimmune disease. These experiments have shown that immunization against A $\beta$  amyloid is no exception. Although a number of strategies are now being tested in the hope that immunogens will be found that do not cause brain inflammation, it is difficult to predict whether this strategy will succeed clinically. The expectation is that immunogens can be tailored to induce a humoral but not a cellular immune response. Antibodies to A $\beta$  amyloid, by acting either directly in the brain or systemically, should reduce the levels of A $\beta$  and thus restore neuronal function. For example, Ryan (160) used an AAV-1-derived vector to induce hippocampal expression of an amyloid-beta binding fragment of a human antibody in a mouse model of AD and achieved some degree of cognitive improvement; however, both T cells and antibodies have been shown to cause neuroinflammatory disease. Monitoring microglial activation in vivo noninvasively before any clinical symptoms develop may be needed if these clinical trials are allowed to proceed. Initial immunizations were tested in mice and in mouse models of AD. However, none of these developed significant brain inflammatory disease. The variation in human MHC haplotypes, compared to the homogeneous H2 of transgenic mice, could explain why inflammation was finally only detected in humans, although it would have been predictable based on our knowledge on how to induce brain inflammation by immunizing against brain proteins.

More recently, neprilysin, a major extracellular enzyme that degrades A $\beta$  has been proposed as an alternative approach for gene therapy, and as such, has been tested in a number of different experimental models (161). Also, IGF-1 has been shown to be effective in experimental models of neuronal degenerations in another neurodegeneration, namely, in mouse models of amyotrophic lateral sclerosis (162). Even though questions remain on how IGF-1 may be delaying the death of affected mice in this model, the strong experimental results in a disease that is otherwise untreatable has led to the accelerated development of significant clinical trials. Should IGF-1 prove effective in protecting spinal cord motor neurons from progressive ALS, it may also be tried as a neuro-protectant in AD. Equally, siRNA has now been shown to be an effective manner of reducing the overexpression of pathogenic proteins in the case of experimental models of Huntington's disease (e.g. huntingtin), dominant inherited ataxias, and torsion dystonia (163–166).

**29.4.2.2 Parkinson's Disease.** The second most common neurodegenerative disorder is PD in which a progressive loss of dopaminergic neurons in the substantia nigra and other brain stem nuclei occurs. This neuronal loss is associated with the formation of intracellular Lewy inclusion bodies and leads to dopamine depletion from the striatum, with projections to the putamen being most affected. Later in the disease, other transmitter systems involving serotonergic cells in the median raphe, noradrenergic cells in the locus ceruleus and cholinergic cells in the nucleus basalis Meynert get involved in the neurodegenerative process. Therefore, patients with PD not only have the typical motor impairment with resting tremor, bradykinesia and rigidity but also balance problems and autonomic nervous dysfunction and show cognitive and psychiatric features.

The exact mechanisms of dopaminergic neuron degeneration are not fully understood. Genetic factors include mutations in the alpha-synuclein (PARK1) and parkin (PARK2) genes (167,168). Parkin functions as an E3 ubiquitin-protein ligase, and a loss of function results in the failure of intracellular protein processing with consecutive accumulation of various proteins to toxic levels (169). Although sporadic and inherited PD have different causes, they likely will intersect in common pathways (170,171). The central cause of sporadic PD seems to be a mitochondrial complex I inhibition, and complex I deficiency may cause alpha-synuclein aggregation, contributing to the degeneration of dopaminergic neurons (170,171).

Gene therapy for PD was first developed in rat models using transduction of a single gene encoding tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis (86,172). Limitations of this approach included the side effects of the helper-dependent HSV1 amplicon vector used at that time, limited expression and expression of TH as the only gene. In the past 10 years, gene therapy approaches for PD have been further developed

in the following three directions: (1) transduction of multiple genes essential for the synthesis of dopamine to restore dopamine levels; (2) transduction of genes encoding growth factors, differentiation factors, transcription factors and antiapoptotic proteins to prevent ongoing neurodegeneration of nigrostriatal dopamine neurons; and (3) improvements and further developments of vector and promoter systems to reduce toxicity and immune responses, increase longevity of expression, and regulate transgene expression.

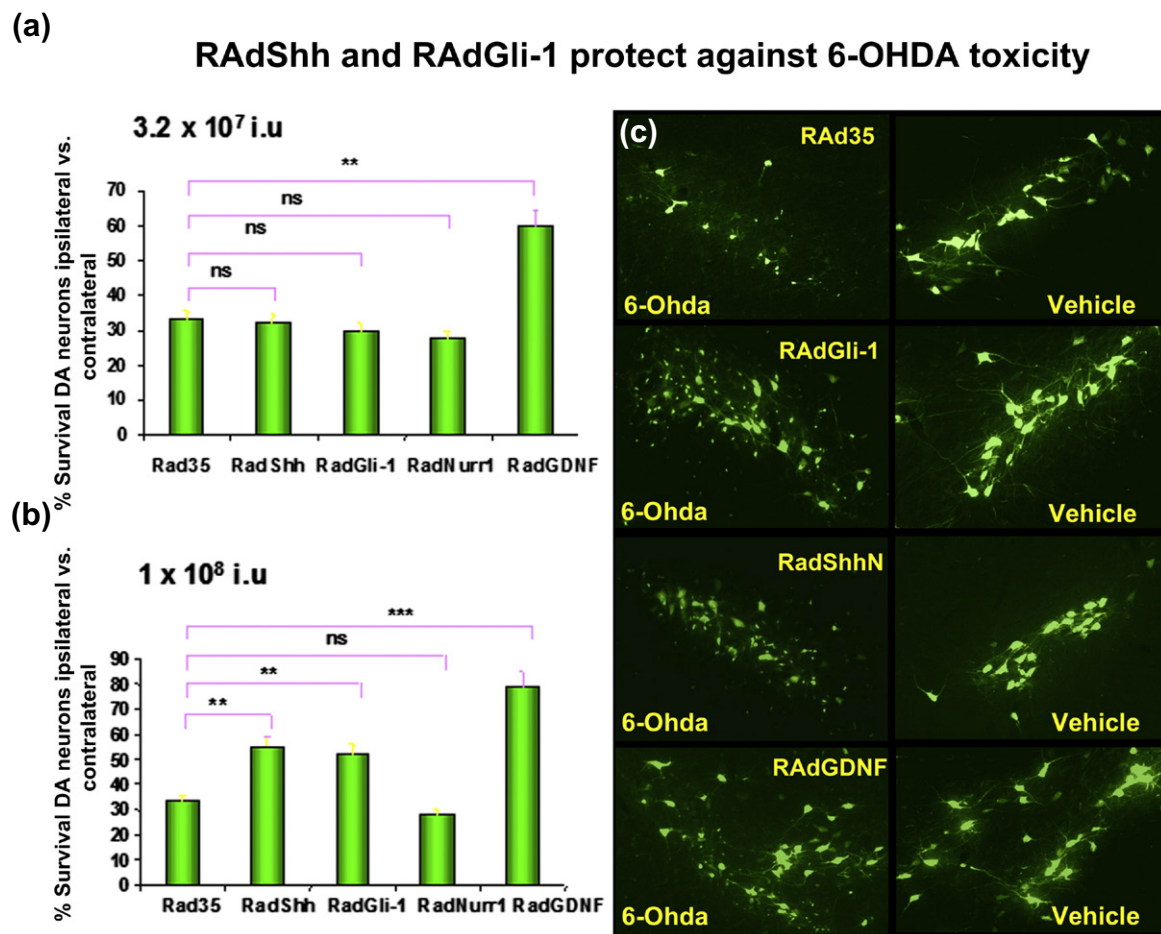

Coexpression of multiple proteins are required for the efficient production and release of dopamine, and recent attempts have been made to express these to improve the levels, synthesis and regulation of dopamine production in gene therapy trials. These enzymes and their functions are as follows: (1) TH converts tyrosine to L-DOPA in the presence of tetrahydrobiopterin (BH<sub>4</sub>), (2) GTP cyclohydroxylase 1 (GCH1) is the rate-limiting enzyme in the biosynthesis of BH<sub>4</sub>, (3) aromatic amino decarboxylase (AADC) converts L-DOPA to dopamine, and (4) vesicular monoamine transporter type 2 (VMAT-2) concentrates dopamine into synaptic vesicles. The following gene combinations have been successfully used in rat and primate models of PD using AAV, HSV1 amplicon or lentiviral vectors: TH and GHI; TH, GCHI and AADC (173–175); TH, GCHI, AADC and VMAT-2 (176). To date, clinical trials have been completed or are under way evaluating vectors encoding five transgenes (of which one is a combination of three transgenes), glutamic acid dehydroxylase (GAD); AADC; the combination of TH, AADC and GCH1; neurturin; and glial-cell-derived neurotrophic factor (GDNF). The mechanistic rationales for using each of these transgenes are explained below. Neuroprotective gene therapy should be especially useful in early PD stages, when sufficient nigral neurons remain and could be protected from further degeneration. It has been shown that transduction of GDNF (177) and brain-cell-derived neurotrophic factor (178), as well as other neurotrophic factors related to GDNF, such as neurturin, protect nigrostriatal neurons from neurotoxic insults in rat and primate models of PD (115,179–181). For potential clinical application uncertain consequences of long-term growth factor expression and questions regarding timing and regulation of therapy (182) need to be addressed; however, it will be difficult to mimic the very long-term expression that will occur in humans. Preclinical experiments have shown that convection-enhanced delivery of an AAV-derived vector encoding GDNF leads to widespread long-term expression of the neurotrophic factor in primate striatum and some functional recovery in a monkey model of PD (183). This approach is currently the subject of a Phase I clinical trial that commenced in 2009. The results of a Phase II, sham-surgery-controlled double-blind clinical trial using AAV to induce neurturin expression in the putamen were reported in 2010 (184). No significant differences in primary end point between controls and AAV neurturin

were observed at 12 months after vector administration, although some modest improvements were seen in a subset of patients at 18 months after administration.

Alternative growth-factor-based gene therapies are being developed based on the protective properties of sonic hedgehog, a secreted neurodifferentiation factor (185,186). Sonic hedgehog has many functions during brain development, one of which is to ventralize the developing brain, including the production of midbrain dopamine neurons. Thus, potentially, the administration of sonic hedgehog could act on local precursor neurons to differentiate them in the direction of nigrostriatal dopamine cells (Figure 29-8). Other paradigms of gene therapy for PD that are currently being tested in animals models include the transduction of dopaminergic neurons with JNK-interacting protein-1, apoptotic protease activating factor-1 (187); dominant negative inhibitor, neuronal apoptosis inhibitor protein (NAIP; (188)); Hsp70 (189), and Parkin (190,191) and are reviewed elsewhere (192).

Owing to the existence of potentially unknown side effects of the gene therapies, especially in the very long-term, it will be important that novel strategies include safety procedures for regulating and inhibiting gene expression. This raises further complexities, given that regulatory requirements are easier to fulfill the simpler the novel genetic constructs are. Paradoxically, it is easier and cheaper for the biotech industry to get approval for clinical trials utilizing less-safe unregulated genetic constructs! Owing to a large number of current considerations, it will be unlikely that either of the trials that will go ahead in the near future will be done using regulatory systems.

Another proposed gene therapy paradigm is the conversion of excitatory to inhibitory output neurons arising from the subthalamic nucleus (STN). To do so it has been proposed to transduce excitatory glutamatergic neurons of the STN with AAV vectors expressing glutamic acid decarboxylase (GAD), the enzyme that synthesizes the inhibitory transmitter GABA (193). Inhibition of

**FIGURE 29-8** Effects of gene transfer on substantia nigra dopaminergic neurons. Quantitative results from experiments on adenovirus-mediated gene transfer of  $3.2 \times 10^7$  IU (a) or  $1 \times 10^8$  IU (b) of RAAd-35, RAAd-GDNF, RAAd-ShhN, RAAd-Gli-1, or RAAd-Nurr-1; all vectors were tested against 6-OHDA-induced neurodegeneration of nigrostriatal cells retrogradely labeled with fluorogold. The morphological analysis is shown in (c). The side injected with 6-OHDA is shown on the left, and the control side is shown on the right. Injection of RAAd-GDNF, RAAd-ShhN and RAAd-Gli-1 protected a significant amount of nigrostriatal neurons compared to animals injected with the negative control vector RAAd-35. Note the survival of large fluorogold+ neurons in the ipsilateral site of animals injected with RAAd-ShhN, RAAd-Gli-1 and RAAd-GDNF compared with RAAd-35. Survival of nigrostriatal neurons was expressed as a percentage of unlesioned contralateral neurons.

the STN through other approaches such as deep brain stimulation is known to be effective clinically. This paradigm has already been implemented in a clinical trial, the first clinical gene therapy trial in humans suffering from PD. The results of this open-label Phase I trial were reported in 2007 (194) and suggested that the treatment was safe and offered significant benefits. The results of a Phase II sham-surgery-controlled double-blind trial using the same approach were published in 2011 (195) and confirmed a therapeutic benefit of the gene therapy. The benefit is modest and arguably not better than what would be expected from deep brain stimulation, but this nonetheless can be considered a landmark study since it is the first well-controlled clinical trial to show a benefit of gene therapy for PD, as assessed by the primary end point defined in the design (196). An alternative to using neurotrophic factors to encourage the survival of neurons is to prevent their death by interfering with apoptosis. The apoptotic protease activation factor-1 (Apaf-1), a gene in the apoptosis cascade, has been used to prevent dopaminergic cell death in a mouse model for PD.

The rationale for using AADC as a therapeutic transgene is that its expression in striatum will lower the doses of L-DOPA needed, thus allowing patients to remain for longer on safe, and effective, doses of this drug. A Phase I trial using AAV to induce AADC expression in the putamen has been completed and results suggest that the treatment successfully increases AADC activity in the target region and produces modest clinical benefits (197). A large Phase I/II trial is going on in England and France to evaluate a lentiviral vector derived from EIAV encoding a combination of TH, AADC and GCH1, but thus far no results have been reported in peer-reviewed publications.

#### 29.4.2.3 Brain Tumors.

**29.4.2.3.1 Definition.** Gliomas are the most common primary intracranial neoplasms and are divided into astrocytomas, oligodendrogliomas, oligoastrocytomas and glioblastomas (198). Glioblastoma is the most fatal primary brain neoplasm with an incidence of three to six in 100,000. Molecular lesions in glioma cells include deregulation of the cell cycle, alterations of apoptosis and cell differentiation, and histopathology shows endothelial proliferation, neovascularization and tumor cell migration and invasion. During progression from low-grade astrocytoma (WHO grade II) to anaplastic astrocytoma (WHO grade III) to glioblastoma multiforme (WHO grade IV) genetic alterations accumulate; however, a clear-cut accumulation of identical lesions across patients typical of each grade of glioblastoma, as has been described for colon cancer, has not yet been described.

**29.4.2.3.2 Gene Therapy.** Originally, the concept of gene therapy for glioblastoma was to transplant fibroblasts genetically engineered to secrete retrovirus vectors carrying a prodrug-activating enzyme gene (199). As retroviruses would only be able to integrate their genetic

material into dividing cells, this concept seemed to be safe for the selective transduction of highly proliferating tumor cells; however, clinical application of this approach did not show a clinical benefit for patients (200–202). The most important limitation of gene therapy for glioblastoma is the heterogeneity of the tumor tissue, with highly proliferative tumor areas alongside areas of necrosis and nondividing tumor cells migrating into the surrounding parenchyma. Subsequent development of gene therapy for glioblastoma has concentrated on

1. combination of different therapeutic genes for synergistic action
2. combination of drug therapy with gene and immunotherapy
3. improved methods of vector administration based on convection-enhanced delivery
4. imaging-based control of vector application and therapy read-out.

The various gene therapeutic strategies that have been studied to treat glioma models have been reviewed recently (203).

- Vectors encoding prodrug-activating enzymes (e.g. thymidine kinase, cytosine deaminase from various bacteria or yeast, guanine phosphoribosyl transferase, cytochrome P450 deoxycytidine kinase, folylpolyglutamyl synthetase, carboxylesterase)
- Vectors designed to correct genetic defects, e.g. by replacing defective cell cycle regulating proteins (p53, p16, p21, PTEN, Rb, p300 etc)
- Vectors encoding factors inhibiting angiogenesis (endostatin, angiostatin, antisense VEGF, dominant negative VEGF receptors, antisense EGF, dominant negative EGF receptors, antisense basic FGF and IGF1)
- Vectors immunomodulation (e.g. IL2, IL4, IL6, IL12, IL13, GM-CSF, TNF- $\alpha$ , interferon- $\gamma$ , antisense TGF- $\beta$ , TGF- $\beta$  soluble receptors, Flt3L)
- Conditionally replicating “oncolytic” viruses based on HSV1, AdV and other viruses.

#### 29.4.2.3.3 Enzyme/Prodrug Combinations: HSV

**Type 1 Thymidine Kinase/Ganciclovir.** This constitutes the most classical gene therapy approach for GBMs, namely, the use of the thymidine kinase from HSV1, which has been extensively employed experimentally and clinically. On administration of ganciclovir, phosphorylated ganciclovir is the toxic final product that mainly kills dividing cells; thus its great potential in treating brain tumors.

The HSV1-TK/GCV system displays significant bystander effects that are thought to amplify its cytotoxic activity. The bystander effect has various components that either stimulate the antitumor immune response or need cell-to-cell contacts to transfer GCV triphosphate to untransduced cells.

HSV1-TK has been delivered using cationic liposomes, HSV, adenovirus, retrovirus vectors, and even replicating vectors. When HSV1-TK is delivered using replicating HSV vectors, GCV itself inhibits the propagation of the vector. This has allowed replicative virus to be used, with the aim of increasing the percentage of tumor cells, which can be transduced, using GCV as a useful safety mechanism to prevent uncontrollable viral spread.

Exciting preclinical data for HSV1-TK/GCV resulted in various Phase I–II clinical trials of HSV1-TK gene therapy mediated by retrovirus, used immediately following surgical resection in patients with recurrent GB. Retrovirally transduced fibroblasts expressing TK were administered by intracerebral injection immediately after tumor resection. The data were suggestive, but the fact that they originated from small uncontrolled trial meant that their real significance still needed to be tested in larger Phase III trials.

Preliminary data highlighted that gene transfer was low, and that, therefore, insufficient numbers of tumor cells would have been transduced. Nevertheless, pharmaceutical interests led to the conduct of a large multicenter Phase III trial with hundreds of patients. In spite of substantial funds devoted to this trial, when patients on the gene therapy arm were doing worse than those on the control arm, the trial had to be stopped. The full extent of the lessons to be extracted from this trial for both the ethics of clinical trials of novel complex technologies and the role of the biotechnological industry in the advance of such techniques remains to be fully explored. The failure of the large Phase III trial has now consigned the use of retroviral vectors expressing TK to the archives of medical experimental history. In doing so, it has also compromised an otherwise powerful experimental approach, namely, HSV1-TK itself.

An intelligent alternative to these approaches has been provided by Seppo Ylä-Herttuala, who compared side by side the effectiveness of TK when expressed from retroviral vectors and from first-generation adenoviral vectors. These studies showed in controlled trials that the AdV were more effective than the retroviruses (204–206). This research has now been expanded and a Phase III trial is now in the final planning and implementation stages. Larger Phase II trials have demonstrated a statistically significant effect of AdV expressing TK+GCV in patients suffering from GBM. Other alternative conditional cytotoxic approaches, such as cytosine deaminase and 5-fluorouracil and carboxypeptidase G2 and proalkylating agents, are also being developed for the treatment of gliomas.

**29.4.2.3.4 Correction of Genetic Defects in GBMs.** Although the genetic alterations that give rise to a cancer cell are numerous, there are some frequently occurring gene mutations in glioblastoma multiforme. Perhaps, the most common genetic alteration is in the p53 tumor suppressor gene and upregulation of the EGF-R, which are mutated in a large percentage of the

human tumors. Tumor suppressor genes encode for proteins that suppress cell division; therefore, by introducing an unmutated tumor suppressor gene into cancer cells, apoptosis can be induced and tumor growth inhibited.

Inactivation of p53 occurs early in glial tumorigenesis, and thus, replacement of mutated p53 gene has been described for many tumor models. Adenoviral delivery of wt p53 into glioblastoma cell lines was attempted, and p53 inhibited proliferation and mutant p53 induced apoptotic cell death. Mutations of the retinoblastoma (Rb) gene and/or p16 gene are also common. Restoration of p16 expression into p16-deficient glioma cell lines, D-54M, U-251MG and U-87MG produced growth arrest. In addition, abnormalities in the apoptotic cascade are almost always present in GBMs, and activation of apoptosis promoting pathways such as the Fas-FasL system have been used to induce glioma cell killing.

#### **29.4.2.3.5 Inhibiting Blood Vessel Formation.**

Important and highly active angiogenic factors were initially discovered through tumor-resection-induced growth of distant tumor sites. Angiostatin and endostatin have been utilized in models of GBM. Growth inhibition was observed and encouraged clinical trials. The turnover time of these small peptides is very fast and it has been difficult to deliver enough of these proteins during long-term periods in humans, and therefore, long-term high-level delivery using gene therapy vectors has been proposed. Gene therapy applications of these ideas are now being tried in clinical trials (see below).

**29.4.2.3.6 Activation of the Immune Response.** Although it is difficult, if not impossible, to stimulate an immune response from the CNS itself, once an immune response has been stimulated systemically activated T lymphocytes have relatively few limitations in finding and destroying tumors located within the brain. The blood–brain barrier, the absence of classical lymphatic drainage from the CNS, and the lack of antigen-presenting dendritic cells (DCs) from the naïve CNS are barriers to the priming but not of the effector phase of the immune response. Tumor cells can indeed be targets of the immune system. The appearance of progressive multifocal leukoencephalopathy in immune-manipulated human patients suffering from multiple sclerosis and Crohn disease demonstrates that the immune system is constantly monitoring the endogenous brain milieu. Therefore, stimulation of the brain immune response is being attempted either through systemic vaccination, systemic stimulation of the immune system or even direct intracranial injection of DCs. A particularly promising approach is the stimulation of the immune system from within the brain proper. Ali et al. (207,208) have recently demonstrated that administration of the powerful differentiator of DCs Flt3L injected directly into the brain in combination with HSV1-TK is able to eliminate rather large brain tumors from the CNS of rodents.

**29.4.2.3.7 Enhancement of the Immune Response Using Cytokines.** The use of cytokines, such as TNF- $\alpha$ , has been attempted but without encouraging data of either preclinical or clinical outcomes. Whether TNF- $\alpha$  might be beneficial in conjunction with other tumor-killing strategies remains to be explored. IL-4 has also been used for glioma treatment because of its induction of very strong immune response in the brain parenchyma and antiproliferative effects on glioma cells. Again, combination therapies may be more effective, although in trials of IL-4 in experimental models it has been shown to be effective. IL-2, IL-12 and IFN- $\gamma$  have also been tested as potential adjuvants for the treatment of brain tumors. More interesting are the novel approaches in which IL-4 has been expressed fused to the translocation and enzymatic domains of pseudomonas exotoxin. This has now been tested in a number of clinical trials and has been touted to demonstrate positive effects in humans. This is now leading to larger clinical trials, and the results thereof are eagerly expected, as they are the only ones that may indicate the real long-term value of these novel experimental approaches. IFN- $\beta$  has now been tested on its own in a number of clinical trials. Lack of striking results has impeded the progression of these therapies into Phase III trials, which would be needed to demonstrate the real value of these novel approaches.

**29.4.2.3.8 Manipulation of Dendritic Cells as a Tool for Brain Cancer Immunotherapy.** An important approach is to increase the number and activity of primary APCs, e.g. the DCs. GM-CSF and Flt3 ligand differentiate hematopoietic precursors into DCs and attract them to the tumor site, also activating the DCs to process the tumor antigens, migrate to the local lymph nodes, and present antigen to naïve T lymphocytes to induce antitumor effects.

Antigen-pulsed autologous DCs are also being used to stimulate antitumor cytotoxic T-cell responses, an approach successfully used experimentally and also in Phase I/II human trials.

Given our still poor understanding of the brain's immune system, the challenge of immune stimulation against brain tumors is whether clinically effective responses can be induced in the absence of brain autoimmune disease (209). Importantly, induction of immune responses against melanomas, even in cases causing vitiligo, have never induced brain disease. Vitiligo destroys skin melanocytes that contain melanin, a protein that is also expressed within the nigrostriatal human neurons. On the other hand, non-small cell lung cancer that develops antitumor immune responses is many times accompanied by immune-mediated cerebellar degeneration, which is evidenced clinically as a paraneoplastic disorder.

Various trials of DC vaccination, in which gene therapy is used to deliver cytokine genes, or antigens, are currently progressing at various centers around the world. Recent resurgence in the interest in regulatory T cells, that are potentially inhibitory to the antitumor immune

responses are also forcing a rethinking on how to prime the subtype of DC that will stimulate cytotoxic T cells without the simultaneous induction of T regulatory cells.

**29.4.2.3.9 Conditional Replication Oncolytic Viruses.** The idea behind oncolytic virotherapy is a simple one. In the course of their natural life cycles, viruses often kill the cells they infect, and this is often cell-type specific. If viruses could be found or engineered that would replicate specifically in cancer cells, this would presumably be of therapeutic benefit. In fact several viruses with a naturally greater ability to kill cancer cells have been identified and several more have been developed by genetic engineering. Progress in using oncolytic viruses to treat glioma is discussed by Zemp et al. (210). Uses of the ICP34.5 mutant HSV vector G207 and the E1B-55 kDa mutant Adenovirus ONYX-015 are discussed above in the sections on those vectors. In addition to these, clinical trials have been performed using reovirus (211), and Newcastle disease virus (106), and a clinical trial using measles virus is in preparation (103).

Some of these systems are currently being evaluated in clinical gene therapy protocols (<http://www.gemcris.od.nih.gov>). The 27 protocols currently described as targeting glioma can be broken down as follows:

- Prodrug therapy (5 trials)
  - HSV-1 thymidine kinase gene mediated by an AdV with subsequent ganciclovir or valaciclovir (2 trials)
  - HSV-1 thymidine kinase gene mediated by a retroviral vector with subsequent ganciclovir or valaciclovir (1 trial)
  - HSV-1 thymidine kinase expression mediated by producer cells that are stereotactically implanted with subsequent ganciclovir treatment (1 trial)
  - E. coli* cytosine deaminase expression mediated by producer cells that are stereotactically implanted with subsequent 5-fluorocytosine treatment (1 trial)
- Cell cycle regulation (1 trial)
  - p53 gene mediated by a recombinant AdV vector
- Antiangiogenesis (2 trials)
  - (a) Episome-based antisense cDNA transcription of insulin-like growth factor I (1 trial)
  - (b) AdV-mediated expression of EGFR-CD533, a dominant-negative EGFR (1 trial)
- Immunomodulation (12 trials)
  - (a) Autologous tumor cells transduced with IL-4 using retrovirus and injected peripherally as vaccine (1 trial)
  - (b) Irradiated autologous tumor cells expressing TGF- $\beta$ 2 antisense RNA from plasmid injected peripherally as vaccine (1 trial)
  - (c) Human interferon- $\beta$ -mediated by AdV (2 trials)
  - (d) Allogeneic or autologous glioblastoma tumor cell lines (IR850) mixed with allogeneic cells

genetically modified with plasmid encoding GM-CSF (IR851) (2 trials)

- (e) Autologous DCs loaded with apoptotic autologous glioma cell fragments, coinjected peripherally as vaccine with autologous fibroblasts transduced with a retroviral vector encoding IL-4 (1 trial)
- (f) Autologous or allogeneic CD8<sup>+</sup> T cells genetically modified with a plasmid encoding a modified T-cell receptor targeting the mutant IL-13 receptor often upregulated on glioma cells (2 trials)
- (g) Expanded autologous bone-marrow-derived stromal cells expressing IL-12
- (h) Cytomegalovirus-specific DCs and T cells (2 trials)
- Replication-competent oncolytic viruses (7 trials)
  - (a) G207 (5 trials)
  - (b) Delta-24-RGD (replication-competent AdV) (1 trial)
  - (c) Recombinant Poliovirus (1 trial)
- Protection of autologous hematopoietic cells
  - (a) Autologous hematopoietic stem cells retrovirally transduced with a mutant methylguanine-DNA methyltransferase to protect them against an otherwise toxic oncolytic drug regimen including high-dose temozolomide and an MGMT inhibitor (2 trials).

**29.4.2.4 Silencing Gene Expression: An Approach to Treat Dominantly Inherited Diseases.** The technologies developed by the gene therapy scientific community mainly concern the expression of genes in target tissues. Thus, as discussed in detail above, various types of vectors have been optimized for expressing genes in any predetermined target tissue. The push for expression of proteins not expressed endogenously has led to the optimization of expression levels. Furthermore, great strides have also been made in the control of tissue-specific expression through the choice of promoters and the regulation of expression through the engineering of inducible expression controls; however, the reduction of endogenous gene expression has been more difficult to obtain. This has left dominantly inherited diseases where the expression of a mutated protein causes the disease without being developed as targets for gene therapy. This includes diseases such as Huntington's disease, dominantly inherited ataxias and dominantly inherited spinal cord degenerations such as the familial cases of amyotrophic lateral sclerosis.

The recent discovery of endogenous cellular mechanisms that regulate precisely and effectively the levels of endogenous mRNA in cells has opened up the possibility of using these methods, generally known as siRNA, to block expression of endogenous genes (212–217). These techniques have now been used experimentally to study the role of individual genes in physiological processes

and more recently as an effective way to inhibit gene expression in a therapeutic context.

Various groups have now demonstrated that siRNAs can be expressed from various types of vectors, and thus, these have been tested in the potential treatment of models of brain (164,166,217), liver diseases (218,219), infectious diseases (220–231) and cancer (199,232–234). The already mature nature of the gene therapy field is likely to allow the rapid translation of these findings into clinical trials. The treatment of inherited dominant diseases has been limited to palliative treatments. Recent successes in experimental models of Huntington's disease (157) (235) are thus likely to be made into treatments in shorter time frames, than gene therapies for those diseases that already have effective, even though not curative, treatments available, such as PD.

### 29.4.3 The Future Challenges of Gene Therapy

During the past 25 years major strides have been made in making the potential of gene therapy into a clinical reality. Vectors have been engineered to accept transgenic cassettes, in some cases up to 30kbp (adenoviral HC-AdV), or even 150kbp capable of encoding large genomic sequences (i.e. HSV-1 amplicons (236–241)), to target vectors to predetermined cell types and to engineer the expression of the therapeutic transgenes by placing these under the transcriptional control of regulatory elements.

Something that has continued to challenge the field is the innate and adaptive immune response to the vectors (209,242,243). Although a few years ago it was thought that the main culprits responsible for immune responses had been identified, recent surprises sometimes coming from the clinical arena have forced a reconsideration of this field. Although it was thought that the use of vectors that do not encode any viral protein, such as vectors derived from lentivirus, AAV, HSV1 amplicons and HC-AdV, would be absolutely safe, it was found that immune responses against capsid proteins could still be induced (244), not only in experimental systems but also potentially in human patients. The seemingly unavoidable clashes with the immune system have now prompted calls for the use of short-term immune suppression during the early phases of vector delivery (245) or until the vectors uncoat and deliver their genomes to the nuclei of transduced cells.

Even if the challenge of immune responses against viral vector capsids is eventually resolved, the potential immunogenicity of transgenes may force the development of tolerance induction in gene therapy (246–250). So far, the issue of immune responses against the therapeutic proteins or their regulatory elements has only been addressed by a handful of papers and constitutes a problem whose magnitude is yet to be determined. However, the development of immune responses against

the transgene in a retroviral vector in immunosuppressed HIV-infected patients (251) clearly highlights that the immune responses against transgenes cannot be ignored. Joint efforts with transplant immunologists are being made to develop strategies that could be applied to humans treated with gene therapy and ways to help patients that might develop deleterious immune responses to vectors and/or transgenes.

The field also needs to develop ways to measure success. A case in point is the treatment of boys suffering from the “bubble boy syndrome” (SCID-X1) due to a deficiency in the gene encoding for the  $\gamma$ c-cytokine receptor subunit. Originally pioneered by the group of A. Fischer in Paris, this gene therapy has now been repeated by investigators in London, Australia and the United States. The results that have been made available so far indicate the treatment to be effective. Indeed, the treatment of SCID-X represents one of the greatest successes for gene therapy, having demonstrably achieved the cures promised more than 25 years ago.

The development of clonal T-cell lymphoproliferations in three patients treated in Paris raised serious concerns. The discovery of leukemia in some of the patients reignited a search for retroviral integration sites in the human genome. Although these had been reported to be “random,” a reexamination of this issue with new techniques demonstrated that most integrations occurred into genes that were transcriptionally active and that in patients who developed lymphoproliferations, insertions were detected upstream of LMO2, a gene that had previously been linked to this disease. So, what went wrong, and could this have been avoided?

Although it may turn out impossible to reconstruct precisely what happened, there are some scenarios that are probable. In SCID-X1, in the absence of the  $\gamma$ c-cytokine receptor subunit, the receptors for the following cytokines are deficient: IL2, IL4, IL7, IL9, and IL15. This leads to a block in T- and NK-cell differentiation. Therefore, in the bone marrow of SCID-X1 patients the lymphoid progenitors lack the receptor for five different cytokines. Gene-therapy-mediated replacement of the  $\gamma$ c-cytokine receptor subunit provides transduced cells with the receptor for five different cytokines involved in the growth, survival and differentiation of lymphoid progenitors. Thus, the engineered cells have an enormous growth advantage against a bone marrow from which lymphoid cells are absent. This is not the case in ADA deficiency, in which the patient’s endogenous bone marrow maintains a low number of endogenous lymphocytes. And before transplantation, by the nature of the *in vitro* transduction protocol, rapidly growing clones will of course be preferentially selected for transplantation. Should the insertion of the retroviral vector into the LMO2 locus provide a growth advantage to those clones, which is highly probable, such clones would be preferentially transplanted. Finally, upon delivery into a patient with a bone marrow devoid of these cells, the

transplanted clones could grow unhindered and those with a growth advantage could eventually outgrow all others.

It is unlikely that this outcome could have been avoided, since previous experiments in mice, rats and non-human primates never gave any indications that this could happen. It is only by reengineering the bone marrow of the SCID-X1 patients that all conditions were met for the development of T-cell lymphoproliferations. Nevertheless, it seems to be the case that this outcome is less likely the earlier the gene therapy proceeds, and thus, through the identification of such factors, gene therapists will be able to avoid these problems in the future. In any case, even for those patients who eventually developed leukemia, the treatment was a success that allowed them a substantial amount of normal life outside the sterile bubble they would have otherwise have been confined to.

Finally, the majority of clinical trials are Phase I trials. These are toxicity trials, rather than therapeutic trials. The lack of a double-blind design, adequate control groups and small numbers of patients involved in Phase I trials makes it generally statistically impossible to draw therapeutic conclusions. Given the history of the field of gene therapy, it is important to use a large dose of patience, detachment and caution in extracting therapeutic efficacy conclusions from these early trials; however, press releases and Internet postings continue to draw therapeutic conclusions from such Phase I trials.

Equally, it will be important to utilize novel molecular pathological assessments of patients being included in clinical trials. For example, global molecular markers of disease (e.g., patterns of genes that segregate disease subtypes by microarray gene expression) should be used in performing Phase I clinical trials for diseases such as glioblastoma multiforme. In glioblastoma recent microarray studies have shown that there are two populations of patients, one with a rapid “typical” progression and a second long-term survivor group that survives for up to 3 years; the impossibility of differentiating tumors from either group by any other means indicates that tests such as these need to be used in the choice of patients for clinical trials (252–254). The increasing availability of molecular markers allowing identification of patients with particular signal transduction amplifications will enable the exclusive enrollment of patients who are likely to benefit from particular interventions. This will increase the rate of success for the appropriate patients and eliminate useless trials for others (252–255).

## 29.5 CODA

Gene therapy has moved from a potential therapy at its inception in the late 1970s to a clinically effective therapy in the second decade of the twenty-first century. Diseases for which there were no treatments available 40 years ago are now treated with gene therapy in experimental settings. In the next decade gene therapy will become

part of the “routine” treatments offered to patients—not as an experimental therapy but as one regular therapeutic option available. New gene therapies are increasingly being tested in advanced clinical trials, leading to a rise of its clinical indications. Gene therapy is now becoming transformed into an additional therapeutic option, and combination with other therapies such as immunomodulation, chemotherapy, radiotherapy, etc., will continue to improve patients’ outcomes. As the field reaches its maturity and the original dreams become therapeutic realities for patients, the visionary imagination of the pioneers’ can only be quietly admired. We have finally acquired the necessary hindsight to confirm their intuitions to realize that indeed, there was “light at the end of the tunnel.”

### Biographies

**Nicholas S R Sanderson, PhD**, is a postdoctoral researcher in the Department of Neurosurgery at the University of Michigan Medical School. His research focuses on the brain's immune response to viral vectors used for antiglioblastoma gene therapy.

**Maria G Castro, PhD**, is a professor in the Department of Neurosurgery and Department of Cell and Developmental Biology at the University of Michigan Medical School. Her research focuses on understanding the cellular and molecular mechanisms of immune responses against brain tumors and developing such knowledge into new clinical treatments for brain tumors.

**Pedro R Lowenstein, MD, PhD**, is professor in the Department of Neurosurgery and Department of Cell and Developmental Biology at the University of Michigan Medical School. His current interests are in understanding growth patterns of brain tumors within the brain micro-environment and using this information to design new experimental therapies for brain cancer.

## Ethical and Social Issues in Clinical Genetics

*Angus John Clarke*

Institute of Medical Genetics, School of Medicine, Heath Park, Cardiff, Wales, UK

### 30.1 INTRODUCTION

Ethical issues abound in all areas of health care. These can relate to the medical management of individual patients or to broader social and political issues, such as the access to care for disadvantaged groups within society and the just deployment of the available resources. Ethical discussions in some clinical areas focus on “end-of-life” or “beginning-of-life” issues, including euthanasia, the withdrawal of futile treatments, and the status of the embryo, while in genetic services there has been an unusually broad range of contentious topics. Important areas have included reproductive issues such as prenatal diagnosis and the selective termination of pregnancies, the proper communication of information within families, the making of decisions on behalf of children or incompetent adults, professional issues such as the role of the clinical geneticist or genetic counselor and the scope of their potentially competing obligations to their patients or clients, their patients’ families and to society more broadly, and the interrogation of common assumptions and attitudes concerning the just treatment of individuals within society.

Two additional factors make any reflection upon ethical issues in the practice of clinical genetics particularly complex. First, there are ethical issues that confront our clients as individuals and families. In most of medicine there are issues that challenge the professional, and there may also be complex issues where society has to declare its view when there are limited resources to be allocated or where the scope of professional practice may need to be regulated. In genetics, however, there are numerous occasions where it is our clients who are confronted by the ethical difficulties. Indeed, it is sometimes our role to formulate the issues for our clients to consider. We therefore need to distinguish among the challenges that we face as professionals, those that are faced by our clients, and those faced by society at large.

Second, our discipline is characterized by the rapid growth of genetic knowledge and, simultaneously, by the rapid development of technologies for generating genetic information and for applying the new knowledge. The sequence of the human genome was first reported only a decade ago but it is already feasible for the genome sequence of individual patients to be determined to achieve a full diagnosis of their condition. In addition to diagnosis, however, the applications of genomics in medical practice now include (i) informing decisions about disease prevention or the surveillance for complications of disease in those at risk from recognized, familial disorders, (ii) assisting in reproductive decisions either by identifying conceptions (after implantation or before) that are affected by specific genetic disorders or by identifying the healthy carriers of recessive disorders, and (iii) guidance on the choice of therapies, especially in the treatment of malignancy.

The challenge for practitioners has shifted from the generation of the DNA sequence of important single genes to the interpretation of vast quantities of data—full exome sequencing or even a whole genome sequence. This new situation of abundant data of which we can make only limited sense may well persist for a decade, or two, or longer. These technical developments are changing the shape of the ethical and social issues confronting us in clinical genetics. The underlying principles and the issues at stake may not be new but the contexts within which clinicians and clients/patients/families are confronting these difficulties are, for the moment, unfamiliar. We have yet to develop common professional habits of practice that allow all parties to feel comfortable and safe. Accordingly, the questions arising in practice repay particular care and attention.

It is my aim here to sketch out the principal social and ethical issues that arise in our work in clinical genetics, considering in particular the impact of recent developments; it is in these areas that practitioners are experiencing particular challenges.

In addition to promoting discussion and debate within our profession, I will be particularly pleased if this chapter contributes to the flow of ideas and discussions across the conventional boundaries between health professionals and patients/clients on the one hand and, on the other, between health professionals and scholars from the social sciences and humanities. Faced with the challenges that confront us all, we can only benefit from the sympathetic understanding and questioning of those with particular skills in these other disciplines.

### 30.2 THE HISTORICAL CONTEXT

Clinical genetics developed after the Second World War in response to the concerns of families and clinicians about the risk of genetic disease occurring within a family. Pediatricians were consulted about the risk of recurrence of congenital malformations or childhood genetic disorders and neurologists were consulted about the risk of healthy individuals developing the neurodegenerative or neuromuscular disorders that affected other members of their families, while some biologists and physical anthropologists collected information that could help to answer such questions. Clinical genetics as we know it arose from the convergence of clinicians tackling these questions with nonmedical scientists interested in human genetics and sometimes caught up in the very human dimension of their studies (1). Genetic counseling emerged as an activity alongside clinical genetics and it has slowly become a profession in its own right (2,3). Human genetics, however, has a longer history than this, which cannot be ignored.

The study of heredity and its influence on human variation, especially on “natural ability,” was developed in nineteenth century Britain by Sir Francis Galton. His focus on quantitative traits was most productive, eventually merging with Mendelian genetics, but he applied this focus with particular enthusiasm to intelligence, social virtues (or their lack), and social achievement. He regarded these traits as primarily genetic and, like many before him, had the goal of improving the genetic constitution of future generations. He coined the term eugenics to describe “the study of agencies under social control that may improve or impair the racial qualities of future generations either physically or mentally.” The term was soon applied to the social movement promoting the improvement of such qualities. The perennial concern about the moral decay of society, widespread among the elders in societies ancient and modern, latched onto theories of heredity in late Victorian Britain as offering solutions to the vices of alcoholism, pauperism, homelessness, and feeble-mindedness. The same set of ideas also reinforced assumptions about the relative evolutionary development of different populations, reassuring the citizens of the major imperial powers that they were justified, indeed destined, to rule over their biologically inferior colonial subjects. Such ideas flourished in literature and the arts, as well as the sciences, and were integral to the mentality of the society at large in

much of Europe and North America. Indeed, the belief or claim that one’s nation is “superior” may lead directly to the need to identify other, less favored peoples over whom to rule, and hence to expansionist policies that would justify the “rightful” exploitation of subject peoples whether in Africa or Eastern Europe. Eugenics may have played a part in fostering the mind-set that led to the disasters and evils of the 1930s and 1940s.

The notion that “Biology Is Destiny” sometimes has a rather narrow set of connotations, relating primarily to gender, but when applied retrospectively to the nineteenth century it can encapsulate the then tacit, taken-for-granted, realities of race and social class as well as of gender. From these common assumptions developed the theories and practices that we now condemn as the eugenic abuses of human genetics. In the early twentieth century, racist immigration policies were introduced in the United States in the guise of intelligence tests; testing to ensure the “quality” of immigrants was then acceptable, whereas overtly racist legislation was not. Legislation to enable the forced sterilization of those with mental handicap, neurodegenerative disorders (4), and a range of other medical and social disorders was introduced in North America, Sweden, Germany, and other countries. Such legislation was not introduced in Britain, but the segregation of the sexes in institutions and the involuntary sterilization of many with mental handicap, especially women, was widespread over many years because the assumptions that led this to appear appropriate, “normal” practice, were so pervasive. Even a full awareness of the horrors of the Nazi campaign of racial hygiene, in which many physicians, anthropologists, geneticists, and other scientists actively participated, and the murderous consequences of the related belief in Aryan racial superiority, did not lead to the discontinuation of eugenicist practices in Sweden and the United States, for example, until the 1970s.

It is unhelpful for contemporary geneticists to be perpetually apologizing for the sins committed by their intellectual forebears, but neither can we afford to forget those horrific events that happened so very recently. As the scientific validity of contemporary genetics and its potential impact on society are now much greater than was the case 70 years ago, it is essential that we identify and make explicit our current taken-for-granted attitudes and our deeply held but often unstated, and perhaps unexamined, convictions. How might these be leading us into errors that we or our descendants will only recognize too late, with hindsight, once great damage has been done to our profession, to our patients, or to society as a whole? This is the hard lesson we should learn from considering the past abuses of human genetics.

### 30.3 GENETIC COUNSELING, TESTING AND SCREENING

A crucial distinction, familiar to every practitioner, is the contrast between the clinical genetic services made

available in response to the preexisting concerns of particular individuals and families, and the population screening programs offered proactively to large groups of the population, who have usually not sought the test that is being offered.

In the context of a specific family, genetics professionals will respond to the particular questions or concerns of family members. For example, (i) parents may be seeking an explanation for a serious developmental problem affecting their child, (ii) an individual at risk of a familial neurodegenerative condition or malignancy may wish to know his or her chance of developing the family's disorder, or (iii) a couple may wish to know the chance of their future children being affected by an inherited condition that has previously affected others in the family. Such a consultation will usually begin with the professional listening to the family's account of their concerns, then performing any relevant clinical assessments or investigations, and finally providing whatever information is appropriate back to the family. This process may be extended in time—perhaps occupying several consultations separated by weeks or months, especially if the precise diagnosis is not readily apparent. Great sensitivity is often required to indications of the client's understanding and emotional responses, whether spoken or unspoken, if the professional is to respond adequately to their needs. It will often be appropriate to provide emotional support, drawing upon the complementary skills of different members of the clinical genetics team, and occasionally referral for more formal psychotherapy may be helpful. In all these cases, however, the professional is responding as best as they can to the client's preexisting concerns.

In the context of population screening, the encounter between professional and client is very different. The professional is actively promoting a specific course of action—that the client/patient should undergo an investigation. The client may never have had any questions or concerns to which the screening test could be understood as a helpful response, so the professional's suggestion of the screening test may itself generate concerns rather than allaying them; it imposes the burden of an unsought decision when one course of action—compliance with the offer of testing—is being heavily recommended in the very act of making the test available at all. Although there are some parallels, this differs from the commercial marketing of a genetic test in several ways; there is an implied professional approval in both settings but this is stronger if no charge is made for screening provided through public mechanisms and the question of cost is not there to serve as a warning cry of “caveat emptor.”

There most certainly are circumstances in which it is thoroughly appropriate for health services to promote a particular screening test or other health intervention—as with the immunization of infants, the measurement of blood pressure in adults, or cervical cytology and mammography in women of specific age groups. In the sphere of reproduction and genetics, however, the promotion of

screening can be regarded as especially contentious; in this context, individual choice is highly valued. Newborn screening for the remediable disorders, phenylketonuria (PKU) and congenital hypothyroidism is universally applauded, whereas there is dissent in relation to reproductive genetic screening, including antenatal screening for Down syndrome or congenital malformation and carrier screening for autosomal recessive diseases. It is unarguable, however, that the context of proactive population screening for genetic disease is very different from that of genetic counseling as a response to preexisting family concerns. This has important ethical implications for professional practice in these areas.

### 30.4 GOALS AND OUTCOMES OF GENETIC SERVICES

In the bad old eugenic past, the principal aim of reproductive genetics was to improve the biological quality of the next generation. This meant encouraging the gifted, successful and virtuous to have more children and discouraging or preventing those with medical or social disadvantages (whether inherited or acquired) from having so many. This would help to overcome what was perceived as the unhelpfully low fertility of the higher social classes and of the “more advanced races.” Such concerns about differential fertility still resonate around the globe; for example, they are reflected, in different ways, in contemporary state policies in Singapore and China and are whipped up from time to time by those politicians in many countries (including developed European and North American countries) who think they stand to benefit from intercommunity strife.

Western society today pays little overt attention to the antiquated concepts of “racial hygiene.” In the contemporary rhetoric of clinical genetics and genetic counseling, our professional goals are therefore quite different from former ideas of “the health of the people” (i.e. of the race). Respect for the autonomy of the individual takes precedence over measures of impact of genetic services on the population as a whole, such as the incidence of genetic disorders at birth or the number of terminations of pregnancy for specific conditions. To describe our goals in terms of such crude population outcomes would now be regarded as frankly and unacceptably eugenic.

However, there is a contemporary context within which comparable assumptions about the effectiveness of genetic services could be seen by some as natural and defensible. This is the economic frame, in which the primary goal of genetic services would be seen as the reduction of expenditure on caring for those with genetic disease or disability, achieved through a reduction in the birth incidence of conditions for which prenatal or carrier screening has been made available. From this perspective, those affected by Down syndrome or  $\beta$ -thalassaemia (for example) would be regarded as a net burden to society.

Despite the contested nature of these claims, over the last 30 years many studies of prenatal or carrier population screening, including prenatal screening for Down syndrome or carrier screening for cystic fibrosis (CF), have essentially argued for the implementation of such programs on the grounds that screening, and the termination of affected pregnancies, is less costly than caring for affected individuals. Although many clinicians may regard these arguments as ethically unacceptable, they are still employed *sotto voce*. Some of those who use these arguments have no moral qualms about doing so. Others may value the offer of reproductive choices per se and therefore support the existence of prenatal screening programs while rejecting the monetary, neo-eugenicist (or “consumer eugenics”) arguments. They feel that screening should be available to all pregnant women and that the absence of such a screening program would, for many, remove the possibility of making important reproductive decisions. The adoption of particular views on this issue by different social groups, including political parties, religious communities and ethnic groups, is heavily influenced by national political alignments so that the political right in the United States, for example, has a very different perspective from much of the political right in Europe. We will turn later to the different context in developing countries.

Crude monetary arguments are not generally used to justify the provision of family-based clinical genetic and genetic counseling services. Such an analysis might show a net cost savings to society, because genetic counseling does sometimes have the consequence of reducing the number of infants born with serious (costly) genetic disorders, through parental decisions not to have children or through the selective termination of affected pregnancies, although clinical genetic professionals may and (I would argue) should refuse to use these arguments to justify their services. To adopt such arguments would concede that families that make other choices, those who decide to have affected children, are making wrong choices. Furthermore, such economic analyses depend on numerous assumptions about the future pattern of health and social care provision and the most appropriate way of discounting the likely future costs of care to be traded against current actual costs of providing the clinical genetics services. These analyses would therefore be complex and contentious even within a purely economic frame.

How, then, can the outcomes of clinical genetics services be measured to permit a comparison of the worth of different models of clinical genetics services or their comparison with expenditure on altogether different areas of health service activity? A number of outcome measures have been proposed and employed in research studies, but it remains unclear whether any of them is suitable for the ongoing evaluation of a clinical service.

- The recall of risk information, concerning the risk of a disease or the risk of its recurrence in a future child, can be assessed after a lapse of months or years, but

recall is the result of many psychological processes including the tendency to polarize probabilities toward 0 or 1, that is, No (it will not happen=0) or Yes (it is certain to happen=1). Further, the significance attached to recurrence risks by clients is itself influenced by the way in which the information is framed in the counseling process (5).

- Reproductive plans can be assessed before and after genetic counseling. This approach prejudices reproduction as the primary concern of our clients, many of whom are not specifically seeking information about reproduction. Furthermore, such plans are merely hypothetical so that their expression will be heavily dependent on the context and framing of the issues by the professional.
- Reproductive behavior has been assessed in some studies but requires prolonged follow-up and a consensus on what would count as a satisfactory outcome for both the clients and the health service professionals.
- Client satisfaction with the service, and levels of anxiety or concern, can be assessed, but may be heavily influenced by the environment in which a service is provided. Clients may not be aware of how the service they have experienced compares with other services, and their views are likely to be influenced by the information they are given in the clinic. For example, clients may be distressed if given an item of “bad news” or they may be resentful if even the most skillful diagnostic process has failed to identify the cause of some serious disorder in their child.
- For the same reasons, questionnaire-based measures of healthy physical and mental functioning are unsuitable outcome measures for genetic services, whereas they may be entirely appropriate for assessing care for osteoarthritis of the hip or ischemic heart disease.
- A more client-focused measure, “perceived personal control,” has been developed as a major improvement on other measures of outcome, avoiding many of the previously identified pitfalls, and can contribute to the assessment of the quality of services provided (6). A similar measure has emerged independently from studies on the outcomes of clinical genetics services in the United Kingdom, encapsulated in the concept of “empowerment” (7). Both approaches can be applied across many different contexts and are not restricted to reproductive genetics.

The ethical importance of the choice of outcome measure is especially grave within a large population-based health service because the professionals in national health care systems or large insurance-based schemes (including health maintenance organizations) can be driven to comply with population-based or corporate goals rather more readily and directly than in a system of truly individual health care arranged between the physician and the patient. If a health service decided to reduce the birth incidence of Down syndrome, CF, or Duchenne

muscular dystrophy (DMD), for example, and to judge the performance of health service staff according to their “achievements” in these respects—perhaps with implications for their rates of pay or job security—then it would be no surprise to see service goals systematically distorting the pattern of health care provided to large numbers of individual patients (8). This is not an argument for the privatization or fragmentation of health care, which brings other problems, but for great vigilance in any large health care system; professionals must watch to ensure that their responsibilities are not subverted, perhaps rather subtly, by the imposition of institutional (state or corporate) policies.

I am arguing here that there is no utilitarian calculus that can determine the worth of clinical genetic services in a neutral, detached or objective manner. Despite these difficulties, there are ways of using research evidence to help decide what services should be made available, and then there are ways of assessing the quality of the services that are provided (9). The decisions about what services to provide will draw on research evidence about the practical consequences of providing particular patterns of service. These decisions are inevitably the product of a political process reflecting both the value that society places upon autonomy in the sphere of reproduction and society’s concern for the welfare of individuals with genetic disorders and their families. Once decisions have been made about what services to provide, their quality can be assessed as a proxy for their outcomes. The provision of specific services to a population may also be assessed as an important dimension of that outcome (10).

### 30.5 NONDIRECTIVENESS IN GENETIC COUNSELING

Respect for client autonomy is one of the core values of the genetic counseling profession. One of the manifestations of this respect for autonomy is the claim that genetic counseling is, or at least should be, “nondirective”: it should not lead the client to make specific choices predetermined by the counselor or the health care system. In addition to respect for client autonomy, however, there are several other important factors that contribute to the cult of “nondirectiveness,” and it is necessary to understand these other factors if we are to use this concept appropriately.

The claim that genetic counseling is nondirective allows the professional to distance herself or himself from emotional involvement in the decision. This may be very helpful, in so far as emotional over-involvement can be damaging. The claim that genetic counseling is nondirective can also function well for professionals by emphasizing that the legal responsibility for their clients’ decisions lies firmly with the clients—an important clarification. Another function of the claim to be nondirective is that it helps professionals reject suggestions that they

may be contaminated by any taint of Nazi eugenics. In all these respects, then, the claim of adherence to the doctrine of nondirectiveness may be attractive and helpful to genetic counseling professionals.

There are several other respects, however, in which the concept of “nondirectiveness” may be problematic and has been challenged. First, at least some elements of clinical genetic services may inevitably be “directive,” leading clients toward specific decisions and outcomes. This applies particularly to population genetic screening programs, most especially in the context of reproductive genetic screening, where the existence of a screening program must in itself carry the implicit message that screening is worthwhile, indeed recommended. This can be referred to as “structural” directiveness and does not imply that the individual professionals involved are actively recommending one course of action or another, although they may be doing so, or the screening program may be so routinized that neither professionals nor clients give active consideration to the issues involved and both parties merely accept screening as standard practice (11,12). In these settings, professionals may have to work hard to help clients appreciate that the decision really is one for them to make.

Second, there are contexts in clinical genetics where it is entirely proper for a professional to recommend a specific course of action to clients (13). This may involve the recommendation that a client at risk of a specific disorder should undergo surveillance for complications of that disorder, as with colonoscopy for those at increased risk of bowel cancer or echocardiography for those with Marfan syndrome. This in turn may involve recommending a predictive genetic test, so that, for example, colonoscopic surveillance for bowel cancer can be targeted at those family members with a high risk, and those who are at population risk can avoid the inconvenience, costs, and hazards of unnecessary investigations.

Genetic counseling professionals may also actively recommend to their clients to share genetic information within their family. When important information about a client’s genetic condition could be relevant to other members of the client’s family, the professional may very reasonably point this out. It could be relevant to the future health of the client’s relatives or to their reproductive decisions. In general, genetic counselors will promote open family communication about any relevant genetic disorder and will indicate the type of problems that can arise if communication is blocked. This is generally acknowledged to be good professional conduct, although it clearly conflicts with “nondirectiveness” if that is interpreted in a narrow and rigid manner.

There is another sense in which an exaggerated respect for nondirectiveness can be unhelpful: when compliance with “nondirectiveness” is taken to require that genetic counselors accept without challenge every statement expressed by their clients, even mere preferences that they may not have considered with much care. This approach

could so constrain the counselor that their ability to help the client is severely restricted. Effective counseling, as in scenario decision counseling, helps the client to think through the consequences of any particular decision or course of action that is planned. This inevitably entails the use of authoritative counselor interventions, such as direct questioning to gather information or confrontation of the client with unwelcome information or with the need to consider some previously unanticipated potential consequences of planned action. Not to make use of such interventions would greatly limit the worth of the genetic counseling (14–16). An inappropriately passive understanding of “nondirectiveness” will undermine the authority and effectiveness of the genetic counselor and reflects a shallow understanding of “counseling” in general, but it is all too easy for such misunderstandings to arise unless professionals monitor their practice with the help of regular supervision.

Finally, there is the danger that nondirectiveness in relation to a complex practical question with extensive moral implications may be felt as abandonment by the client. This has been particularly problematic for those patients recently diagnosed with cancer, who are faced by choices between therapeutic options where the evidence is unclear and difficult to interpret. An impersonal and detached presentation of the options can then, understandably, be experienced as an emotional withdrawal from the client, as abandonment. In other contexts, as within clinical genetics, the practice of nondirectiveness could also be perceived by clients as a lack of full personal engagement unless the professionals take care to make this concept function on behalf of the clients rather than on behalf of their professional selves.

Any claim that genetic counseling should always be “nondirective” would be unhelpful, and any claim that it is so would clearly be false. Respect for “nondirectiveness” is appropriate but only when it is understood as a rich and complex concept that usefully sustains the tension within practitioners between respect for the client’s autonomy and other competing priorities. If this appropriate sense of “nondirectiveness” is to be recognized in practice, we will require sensitive tools for the analysis of language in the specific interactional context of genetic counseling—within a sophisticated methodological framework for the understanding of language in its more general social context. Mechanical or formulaic definitions of what constitutes “nondirectiveness” will be unhelpful.

### 30.6 DIAGNOSTIC GENETIC TESTING

When an individual presents for medical attention because of a clear health problem, there are usually few ethical issues for the physician to consider in striving for a diagnosis. This will usually have to be the first step in meeting the broader needs of the patient and the family for prognostic information and advice about treatment.

However, there are at least two types of problems that may arise: the difficulty of handling diagnostic information about the patient when it has important implications for others and the difficulties that may arise when investigations reveal information of uncertain significance.

Communicable disease, especially sexually transmitted disease, provides another context in which a diagnosis may have important implications for others; health professionals will work with a patient in an attempt to pass on the relevant information to their sexual partner/contacts and there may be legal sanctions when important information is withheld. This situation may parallel transmissible genetic disorders in some respects, although, clearly, not all. Legal force is not usually applied to compel a patient to disclose sensitive personal information in the context of genetic conditions, although legal protection may sometimes be available to health professionals who disclose such information to the at risk relatives of the reluctant patient.

When a physician is investigating the cause of a patient’s symptoms, the differential diagnosis will often include the possibility that the problem may have a genetic basis, although the chance of this will often be small. The physician may well not mention this possibility of a genetic basis for the problem in discussion with the patient or family unless investigations make it likely that this is the case. What chance of the diagnosis being genetic should prompt the investigating physician to raise it as a possibility? How would this differ for different possible diagnoses? Does it change with the particular prognosis, response to treatment, family implications, etc.? Two examples may assist reflection:

- (1) When the diagnosis of DMD is being considered in a young boy with delay of motor and perhaps language skills, telling the parents that such a diagnosis is a possibility will cause distress but may help the parents prepare themselves and the wider family to deal with the implications if the suspected diagnosis is confirmed. Should it be discussed at the initial presentation or only once first-line investigations make it more likely, such as the finding of a greatly raised serum creatine kinase? The answer will often depend on contextual circumstances that cannot be prescribed as a general rule but it would be unusual not to mention the possibility of an inherited disease before either proceeding to analysis of the dystrophin gene or to a muscle biopsy.
- (2) If an adult has presented with dementia, this clinical picture will occasionally be the result of an underlying genetic condition, such as Huntington disease (HD) or one of the less common inherited dementias. This is more likely if the onset of disease is at a younger age than usual, if there is a relevant family history or if the patient has some additional neurological manifestations. Depending on these factors, the physician will need to consider (a) *whether* the

possibility of an inherited disorder should be mentioned, (b) *how* it should be mentioned, (c) *with what emphasis* and (d) *to whom*. The possibility of an inherited basis would often be discussed with the patient (and perhaps one or more relatives) if the diagnosis of HD was being considered as quite a distinct possibility but might not be mentioned if the molecular test for HD was being performed as the least likely of a long list of possible conditions under consideration. Even if mentioned, the patient's anxiety, cognitive impairment or both may limit whether or how this information could be passed to relatives. In practice a spouse or other relatives may also be informed of the suspected nature of the condition as a transmissible disorder, perhaps through being present with the patient in the consultation. This can open up an opportunity to help the family manage communication about the condition more effectively, if investigations subsequently confirm that it is genetic.

While the genetic nature of a condition remains uncertain, it may be difficult for the family to communicate effectively about it: those aware of the possibility may be uncertain what to say, or to whom, and how much concern would be appropriate to share with others when it may all come to nothing. This leaves open the question of how the professional strikes the right balance between backing away altogether from giving a warning in any family or creating needless anxiety in too many families, while of course always respecting each patient's confidentiality.

The other problem area is of investigations yielding information of uncertain significance. This difficulty has always been there in genetics since the earliest days of chromosome studies, which may be regarded as the first genome scanning technology, albeit of very low resolution. As laboratory techniques have progressed, so that the resolution of the available genome scan has improved, both scientific knowledge and clinical experience have accumulated. After the counting of chromosomes, the development of chromosome banding techniques was the next major step forward. It has taken years, sometimes many years, for the medical implications of each anomaly to be appreciated and there can still be real difficulty in predicting or interpreting the reproductive consequences of complex chromosomal rearrangements.

The interpretation of diagnostic results from the molecular genetics laboratory has passed through phases in which uncertainty has been more or less prominent. The early application of genetic linkage analysis to families gave physicians good practice in explaining the limitations of molecular diagnostics and estimating the frequency of misleading conclusions (e.g. double recombinant events). The use of linkage disequilibrium to estimate the probability that an individual carried

CF trained us to attend to a person's population of origin. As mutation testing then became possible for some important loci, it seemed that the ease of interpretation was steadily increasing. Even difficulties such as the distinction between Duchenne and Becker muscular dystrophy caused by mutation in the same gene (the dystrophin gene) could usually be accounted for by the frameshift hypothesis. However, the interpretation of sequence information then became more complex in the clinical context, most prominently in some of the Mendelian cancer-predisposing genes. When a novel sequence variant was found in an individual with a strong family history of cancer, how should it be interpreted? This remains a problem today in the context of familial breast cancer and some of the novel variants found in *BRCA1* and *BRCA2* in those with breast cancer and/or a family history of breast or ovarian cancer; such variants are often known as VUSs (variants of uncertain significance).

Comparable difficulties arise in relation to autosomal recessive disorders. Sequence changes in the CF locus *CFTR*, for example, may be entirely innocent or they may be weakly pathogenic when accompanied by a definitely pathogenic allele on the other chromosome (leading to a late-onset and rather mild predisposition to chest infection), or they may predispose to a very mild phenotype, such as "congenital bilateral absence of the vas deferens" (CBAVD), resulting in male infertility. This gives rise to the need to distinguish between the clinical condition and the gene: simply having two mutations in two *CFTR* alleles is not necessarily equivalent to having the clinical disorder known as CF; this emphasizes the problems of talking about the "gene for" something (whether that something is musicality, sexual orientation, Viking ancestry, a character trait or a disease, such as CF).

With the switch from mutation searching in Mendelian genes to high-throughput genetic technologies, some other major changes have occurred. First, while genome-wide association studies (GWAS) have proved useful in some research applications, their clinical utility in the common, complex degenerative diseases of developed societies has not been demonstrated. While many highly significant associations have been found between single nucleotide polymorphisms (SNPs) and disease, the relative risks involved have generally been very small and the proportion of the genetic contribution to the risk of disease that can be accounted for (i.e. used in risk "prediction") is generally in the range of 10–20%. The problems of accounting for the remaining 80–90% of heritability is known as the "missing heritability" (17). In addition, there are unresolved questions about (i) how to demonstrate (how to avoid overlooking) important gene–gene interactions (i.e. departures from the simple multiplicative combination of relative risks) and (ii) the appropriate models of selection that must operate to account for the high levels of genetic polymorphism observed within human populations.

Moving beyond SNP-based association studies to the direct detection of abnormalities in high-throughput studies, the first technology to enter regular clinical practice has been comparative genomic hybridization (CGH) arrays to detect copy number variants (CNVs). This has shown not only the high frequency of CNVs of varying sizes that are compatible with normal development and functioning but also the contribution of specific deletions and duplications to disorders of physical and mental development and vulnerability to the acquisition of psychiatric disease (18). Particular CNVs that appear compatible with normal development may contribute to severe developmental problems in the presence of environmental triggers or other specific CNVs (the “two-hit” model of developmental disorders) (19). The caution required in interpreting these investigations has recently been emphasized by the American College of Medical Genetics (ACMG) (20).

The next technology to impact on genetic diagnostic services is that of whole genome sequencing (WGS), or at least whole exome sequencing (WES) of protein-encoding genes. This is not yet widespread in regular clinical practice but experience is being gained through research-led studies both of healthy individuals and of those with overt disease (21–23). The “Thousand Genomes Project” and other studies are revealing very high levels of rare variants, some of which are likely to make a substantial contribution to disease or risk of disease (24). However, the sheer number of rare or completely novel variants identified in each human genome sequenced is such that the interpretation of WGS data is difficult and demanding; the generation of sequence data is no longer the rate-limiting step in diagnostics but rather its interpretation (25). Bioinformatic techniques make such interpretations feasible, although they depend, for now, on numerous assumptions that will not always be correct. Computer modeling of the functional consequences of “mutations” can give helpful results but is not infallible. It will take years, perhaps decades, of data accumulation and analysis and of functional molecular studies for the interpretation of most DNA sequence variants to be interpretable in a clinical context with reasonable confidence. The interpretation of WGS data is likely to shift frequently over the next few years as new knowledge accumulates, so it is highly unstable (26). In the meantime, we have two major problems: (i) how do we organize high-throughput sequencing and the associated data storage and analysis, conducted to answer clinical questions? (ii) what do we say to patients?

One possible approach to the clinical use of WGS—we could call this a “minimalist” or “focused” approach—would be to carry out the best analysis possible for the clinical question at hand and to ignore any findings likely to be incidental to this, however important for other reasons. Data would not be stored, so the problems of refined future analyses, of data attrition and of completely incidental results would disappear. For

example, it may become cheaper and easier to perform WGS (or exome) analysis when there are many genes that need to be sequenced for diagnostic purposes. Once one or more gene variants are found that may plausibly be contributing to the disease, it may be regarded as the achievement of the desired output. There would be no need for further genetic analysis; the sequence changes could be confirmed (e.g. by Sanger sequencing), the report produced, and then the data could be deleted. If further testing came to be required for some other purpose (in relation to another disease, or to produce information about carrier status for reproduction or pharmacogenetic information for “therapeutic guidance”) then WGS would have to be repeated. However, it may soon be inexpensive enough not to be the rate-limiting step.

A very different approach would be (i) to report on all the incidental findings unrelated to the reason for testing, in addition to answering the questions asked; (ii) to keep the full WGS (actively maintaining the data over time to prevent its degradation) so that it remains available for interrogation for any future health questions; (iii) to conduct functional studies on rare variants in the patient’s WGS that bioinformatic studies or published literature suggest may be relevant to the risk of a disease; and (iv) to produce updated WGS interpretations from time to time, as knowledge develops year by year. This approach clearly involves a much more active, open-ended and costly commitment on the part of the laboratory team performing the genomic analysis.

Comparison between these two approaches makes clear some of the ethical problems that are beginning to declare themselves in the clinical practice of this new world of genomic medicine. They can be summarized in the set of questions below. As yet we have no clear consensus on how to handle these difficulties, although the ACMG has given helpful guidance on the parallel difficulties from array CGH studies (20).

1. Should care be taken to avoid generating any additional information beyond that required to answer the specific clinical questions being asked?
2. Is there an obligation to interpret all sequence information generated or only what is thought to be relevant to the clinical question asked? Would this obligation lie with the diagnostic laboratory or with the clinician requesting the test?
3. When information is generated about a child’s genome sequence, should there be additional controls on access to the data and its interpretation?
4. Should sequence information generated in a diagnostic laboratory be stored for the long term, released to the patient/client, or destroyed once it has been reported?
5. When a laboratory stores sequence information, should it undertake and report periodic reanalyses as the accuracy of sequence interpretation improves?

6. When a laboratory generates and stores sequence information, should this be managed actively to prevent its degradation?
7. In addition to an individual's medical team, who, if anyone, should be able to access their stored sequence data?

The second question is what to say to the patient or at risk individual. It will often be impossible to say nothing, especially if further family studies—samples from other relatives—may be helpful in resolving the uncertainties. There is already some experience of these issues in practice (27–30) but the scale of the difficulty is altogether new. It will be necessary for the diagnostic laboratory to make decisions as to what information, which variants, to pass on to the patient's clinical team, and then the clinical team will need to decide which of these to work on actively (e.g. sampling other relatives), which to declare as being of uncertain significance but with the possibility that their interpretation may become possible, and which to file away without mention. This will be an important area to watch as practices evolve.

The use of genomic information to guide clinical decisions about treatment is well established in oncology and is likely to increase and broaden in scope. Such practices raise social and ethical issues somewhat different from traditional diagnostic practices because the wider family implications may not be fully appreciated (31) and the imperative to provide the best treatment can mean that the decision process has to be rapid and unwelcome prognostic information about the individual may be generated, as well as difficult issues to discuss with relatives (32,33).

### 30.7 PREDICTIVE GENETIC TESTING

Individuals at risk of developing a serious inherited disorder will sometimes wish to find out if they have inherited the relevant gene. For the autosomal dominant neurodegenerative disorders, such as HD and some of the rare familial forms of early onset Alzheimer disease, highly accurate predictive testing is possible. Uncertainty as to whether the individual will develop the disease is replaced by uncertainty as to when (and how) it will manifest. In the context of the autosomal dominant familial cancer disorders, testing may also be possible, although there are limitations to the predictive power of these tests, because some individuals with their family's gene mutation, predisposing, for example, to breast or colon cancer, will escape the relevant cancer, whereas others, without the relevant mutation, may nevertheless develop the cancer. Inheritance of the predisposing mutation increases the statistical risk of developing the cancer from the population risk (of more than zero) to a high risk (but still less than 100%). In *BRCA1*-associated familial breast cancer, the increase in (lifetime) risk may be from approximately 10% up to 70–80%.

The ethical issues that can arise in the course of predictive genetic testing are numerous, and many are considered elsewhere in this chapter. Here, we will discuss just two particular topics. First, it is instructive to consider what has been learned from the numerous studies performed on the process of genetic counseling and predictive testing. Clients seeking predictive genetic testing and recruited to research studies have been asked to complete psychometric and open-ended questionnaires; in some studies, they have also been interviewed by a researcher. In general, it has been found that the process of genetic testing for those at risk of a familial disorder has been well tolerated, even when unfavorable results have been generated (34,35). Surprising, originally perhaps counterintuitive, findings have also emerged, however, such as the distress and social dislocation sometimes found in those given a favorable predictive test result. A favorable result can lead to feelings of guilt in young adults with siblings who are already affected or who are shown to be at high risk of disease—a form of survivor guilt. Family ties, perhaps strengthened from sharing the impact of the disease, may weaken for those no longer directly involved with the condition (36–38). Those who have made important life decisions, perhaps about career, relationships, or reproduction, may wish they had acted differently when they find that the basis on which the decisions were made—their genetic risk—has been removed.

It is usually recommended that those going through the process of “counseling plus testing” are supported by a companion, who is often their partner and who is, usually, not himself or herself also at risk of the disease in question. It has become clear that such support persons may themselves benefit from support and from at least some exploration of their thoughts and feelings in the pretest counseling sessions. If the person at risk is destined to develop HD, there may be serious implications for the future life of their partner too.

Another finding has been the inadequacy of the understanding of predictive genetic testing to emerge from psychometric assessments of its impact. Any simple interpretation of anxiety as a negative, unhelpful, or undesirable response to testing or test results has been challenged by qualitative evidence that such measures of anxiety may reflect an active process of confronting and engaging with potentially unwelcome facts (39). To use evidence of increased anxiety after testing to make a policy decision not to provide such testing services would be completely inappropriate. Furthermore, some of those in whom the measures of anxiety are increased before receiving the test result may subsequently be in less need of emotional support than others in whom the pretest measures of anxiety had been lower.

The second issue to consider is the family dimension of predictive tests, sometimes amounting to a conflict of interest between family members. The genetic testing of individuals at 25% prior risk of an autosomal dominant

disease provides the starkest examples of such conflicts of interest. What if a young man, whose grandparent has HD, wants to know if he will develop the disease too? He wants to marry and start a family but wishes to clarify his genetic status first. His at risk parent appears healthy but has made it clear to all concerned that she or he does not want to undergo testing. If the young man is found to carry the HD mutation, then his parent must carry the mutation, too. There are ethical issues here for the young man, his at risk parent, and the genetics professional. In most families, a resolution can be found to the potential conflict if the professionals encourage discussion within the family and are available to discuss the issues with the various parties—a solution through facilitating communication. Occasionally, however, real conflict persists and professionals have to decide whether to make testing available to one family member if doing so may have adverse consequences for others. The process of resolving such family disagreements can be particularly difficult when a couple unsure of their genetic situation have a pregnancy and wish to make a decision about prenatal diagnosis—the need for haste in making decisions then adds to the difficulties.

Professionals also face the difficulty, in counseling for predictive tests, as to how to challenge those going into tests with the possible outcomes. Our experience is that it is helpful to anticipate problems by thinking through various possible scenarios, but not everyone wishes to engage in this process. How hard should we try to encourage them (40,41)?

Additional difficulties can arise in families with diseases that show marked anticipation, such as myotonic dystrophy. In this case, a diagnostic test (of an infant with possible congenital myotonic dystrophy) may effectively be a predictive test when considered from the perspective of the apparently healthy mother who has not yet recognized her minor symptoms (42). This makes the counseling issues especially difficult if the child is to be given the appropriate diagnosis while the mother—and her parents—are led gently to consider testing for themselves. Similarly, complex, transgenerational issues arise in fragile X syndrome families, where testing of the affected child's maternal grandparents is a form both of carrier testing and, for the possibly premutation-carrying grandfather, of predictive testing for late-onset disease.

## 30.8 CONFIDENTIALITY

Respect for confidentiality is one of the oldest principles of medical ethics—at least as old as Hippocrates and certainly more ancient than the contemporary attachment to autonomy. My own view is that confidentiality must continue to be respected in medical ethics at (almost) all costs. In relation to genetics, however, it is subject to challenge on several grounds. First, genetic information might be sought about individuals by their employers or insurance companies or by the state. Second, the fact that we share

(almost) all our genes with other members of our families has been used to justify the claim that genetic information about one individual “really” belongs to his or her relatives, too, so that respect for confidentiality (genetic privacy) need not apply so strongly within families. However, that argument may be said to beg the question.

### 30.8.1 Third Parties

Protecting the individual's right to genetic privacy from third parties, such as employers, insurers, and the state, has been robustly defended. Although insurance corporations have generally accepted that they should not require genetic testing before making life insurance available to applicants, they have been less ready to concede that prospective clients should be able to have genetic tests performed without passing on that information to the insurance company, as with any other medical information. The counter-argument runs that genetic information is not like other medical information because if the individual is currently in good health genetic information about propensity to disease is essentially predictive or risk modifying and not at all like information about current clinical problems. The danger for the insurance companies is that of “adverse selection” in which their clients will be better informed than they are, and so those at high risk of serious problems may take out more insurance while paying only standard premiums, so that the company, and ultimately its other clients, lose out, and higher premiums have to be charged.

When applying for health or life insurance, most individuals at high risk of serious genetic disease will in any case have to declare their family history and so the insurance corporation will be aware of some of their pretest risks. If they have a favorable predictive test result, they may inform the company, but otherwise the individual seeking insurance may prefer not to disclose the result. The number of adults at high risk of a serious genetic disorder but who are in good health when seeking life insurance is small, however, and the number who are likely to die from the disorder during the term of insurance is smaller, so that the industry is unlikely to suffer much from adverse selection in this context. The potential for adverse selection is probably greater for health insurance, especially in the context of a predominantly commercial health care sector as in the United States, although there is no evidence that such adverse selection has occurred to any great extent.

This problem can be used as a powerful argument for the organization of health services by the state, whether as a single scheme or a few regional schemes (as in the United Kingdom), or through a largely private, but closely regulated, insurance scheme (as in many European countries and Canada).

Employers may wish to gain access to genetic information about their employees, or potential employees, for several reasons. Genetic information might be used

to alter the selection of job applicants or the promotion prospects of staff in post, in favor of those less likely to develop serious disease before retirement. The scope for genetic screening of the workforce for susceptibility to disease is small because DNA-based screening tests for susceptibility to the common, complex diseases are insufficiently sensitive for this to make commercial sense, but that situation may change, especially if ways are found to integrate genetic results with clinical findings on examination, biochemical measurements or imaging. Screening the workforce for susceptibility to specific occupational disorders is also not feasible at present, although a case has been made for screening workers for  $\alpha_1$ -antitrypsin deficiency (A1ATD) in industries where workers are exposed to smoke or dust, as in quarries, mines, building sites, because this condition predisposes individuals to severe, chronic chest disease after such exposure. An argument for caution in genetic testing of a workforce is that the exclusion of susceptible workers from hazardous sites could be used as a cheap but inappropriate substitute for the proper environmental protection that would in fact benefit the whole workforce and the local environment; perhaps both approaches could be adopted.

Those at risk of HD, or in the early stages, report discrimination in the context of insurance much more commonly than in relation to employment (43). Several countries in Europe and North America have developed national agreements to restrict the gathering and application of genetic information by insurance companies or have introduced legislation to prevent discrimination against those affected by, or at risk of, genetic disease in insurance or employment. Predictive assessments of life insurance applicants on the basis of lifestyle information becomes in practice a moral judgment; genetic medicine fits into the same process but the question of blame is more difficult to justify as the individual has no control over their inheritance; this area will repay further detailed work (44). Without proper legal protection, there is the fear that individuals at above average risk of specific disorders may become unable to find insurance cover, and in some jurisdictions this will make it much harder for them also to find employment if health insurance is provided by the employer. This could lead to the formation of a class of people identified by molecular genetic testing who would be excluded from full participation in society—an underclass reminiscent of George Orwell's 1984 and of real societies that practice slavery.

### 30.8.2 Privacy within the Family

Although conventional medical ethics has insisted on respecting the confidentiality of patients except in the most extreme and exceptional cases, this view has been challenged in the context of genetic disease. Information about one member of a family can be regarded as information about their relatives, too (45,46). Harm could result, it is argued, if genetic information is not shared

with relatives—an individual at risk of a disorder may develop complications that could have been avoided if they had been given foreknowledge of the risk, or a child may be born with a serious disorder when the pregnancy could have been terminated if the parents had been warned of this possibility (47). To what extent these “harms” could be avoided, and whether the birth of a child with a genetic condition can be regarded as a “harm,” are complex issues that require further analysis, but most of us can at least agree that family members have a moral obligation to pass on potentially relevant genetic information to their relatives (48,49), even if we might dispute the legal force of this obligation or whether the obligation extends also to professionals, and we might contest the notion of genetic harm implicit in this discourse when it leads toward the notion of a “wrongful life.”

The topic of debate then shifts to professionals and how they can best promote the appropriate transmission of information within family networks, accepting that it may be difficult to contact some family members, that others will be distressed by genetic information that may well turn out not to be relevant to them, and that the duty to contact relatives can prove burdensome to our clients. There may be no easy solution to the problems arising from the duty to transmit information. Perhaps a client has just found out about a sex-linked disorder present in the family; his niece is to be married next Saturday afternoon and will then be going on honeymoon for 3 weeks: what should our client do (i.e. when should he talk with her about the genetic risk)? Perhaps another client has just been told by his physician that his kidney complaint is inherited as an autosomal dominant trait and his four (adult) children are at risk—but Sally has just become engaged, Manfred is sitting his university final examinations in 2 months, Mark's wife is 6 months pregnant, and Maureen has just been admitted to hospital with her second bout of severe depression in 2 years. Whom should he tell about the polycystic kidney disease? Or our client may suffer from male infertility but find it difficult to discuss this with his wider family, even though they may be carriers of the CF mutations identified in him, or could even themselves be (mildly) affected. There may be no “right” time to pass on such information but it usually should be transmitted at some point in the not-too-distant future.

One approach is to view these problems from a family systems perspective and for the genetic counselor to work on managing the situation on behalf of the whole family but through the individuals with whom he or she already has contact. This counseling-based approach is usually successful, in that the blocks to the flow of important information usually dissolve over time and with sympathetic discussion and support from the genetic counselor. But what should the professional do if an individual persists in refusing to transmit the information or breaks off contact with the genetics team?

There are those who argue that the professionals should then be prepared to pass on information about one family member to others without their consent, although always informing them of this decision before implementing it. The circumstances in which such a breach of confidence would be justified have been considered by several learned bodies, although there may still be no consensus about what to do in specific cases or even about how to resolve any differences (50,51).

This could lead us to discuss in detail the various ethical frameworks within which such issues could be addressed but here we have space merely to outline four approaches to ethical deliberation. One approach would be to reflect on and discuss the competing principles at stake, with the principle of autonomy usually trumping the others in our contemporary, individualistic, Western societies. Another approach that is also founded on a positivistic individualism is that of utilitarianism, attempting to weigh, in a notional calculus, the likely outcomes of particular courses of action, and perhaps considering the concrete particulars of the case in its analysis as a bioethical case discussion (for a critical view, see (52)). A third approach is that of “common morality” (53), respecting rationality and impartiality in decision making within an open, public framework of moral rules. The final approach is that of narrative ethics, in which the professionals do not seek to abstract the issues of principle from the particulars of the case, the context, but to focus on the experience of their clients and encourage them to reflect on the future paths they can envisage taking (54). This approach can draw together a professional ethic derived from MacIntyre’s virtue-based morality (55) with the professional skills of humanistic counseling, making use of narrative approaches to promote the personal growth, development, and healing of their clients. It is hoped that this may thereby resolve (or dissolve) many of the ethical difficulties that could otherwise persist and become problematic if a confrontational approach is adopted.

Studies have examined how professionals say they respond in practice to situations in which a client fails to disclose important information to his relatives, once the professional has recognized the problem. It seems that professionals only rarely become seriously concerned and hardly ever in practice breach confidentiality (56). While the obligation to inform relatives carries weight (57,58), empirical research has demonstrated the multiple barriers that operate to hinder family communication and the factors that promote it (59,60). One approach to such problems, and which can be adopted when there are clear health benefits at stake so that the maximization of information flow through families is a worthy goal, is a very proactive professional orientation to passing on information to relatives. This encourages, supports and normalizes the contacting of individuals directly by a health screening program, as in some programs of cascade testing for familial hypercholesterolemia (61).

Some professionals fear that the development of a formalized framework for breaching confidences will inevitably make such practices a mere routine, even an expected or obligatory component of the professional activity of genetic counseling. Although it would be inappropriate to announce that there are no circumstances in which a professional could legitimately breach confidences, many problems would be generated by any regular, systematic policy of transmitting confidential genetic information about one individual to their relatives without consent. Professionals could become less inclined to persist with alternative approaches to resolving these communication problems. Clients, aware that confidentiality could be jeopardized by their counselor or clinician, could tend to be less than frank about their disease or their family structure from their first contact with the clinical genetics team. These potential consequences of altering the rules of professional conduct would be difficult to demonstrate in a quantifiable fashion but would be nonetheless real for that.

### 30.9 GENETIC TESTING IN CHILDHOOD

When is it appropriate to carry out genetic tests on children? There are few issues on which there is so much disagreement among health professionals or between professionals and families and so much variation in practice.

There are circumstances in which all agree that genetic testing is entirely appropriate. If a child has a clinical disorder that requires a diagnosis and which may be genetic in origin, then genetic testing may be the most appropriate investigation. For example, a young boy with delayed motor and speech development and an elevation of the serum creatine kinase may have DMD. A molecular genetic investigation, searching for deletions and duplications within the DMD gene or sequencing for point mutations, may well yield a diagnosis and thereby perhaps avoid the need for the invasive procedure of muscle biopsy. More complicated to consider are the “diagnostic” tests whose results may be difficult to interpret, as with array CGH tests for CNVs and whole exome or whole genome sequencing (see earlier, Diagnostic Genetic Testing).

Predictive testing for a disorder with onset usually in childhood is another context in which childhood testing can be appropriate. Thus, in the aforementioned family, if the boy does have DMD, it may be appropriate to test his younger, apparently healthy, brother. The family is likely to be highly anxious about him—will he develop the same disease—and it may take months or even years before either the diagnosis becomes apparent or the family is reassured. Some might prefer to wait and watch but many families wish to know one way or the other. There may be contexts, however, where parents may find an unfavorable result especially difficult to live with, as when a test indicates that the child has an increased risk of psychosis (62) or sudden death (63).

Another context in which a child might very reasonably have predictive testing for a genetic disorder, even where the condition will often not manifest until adult life, is where the child is at risk of complications for which surveillance can usefully begin in childhood, as in familial adenomatous polyposis coli.

Predictive testing for disorders that usually have an adult onset and that are untreatable is another matter altogether. To test a child, who is too young to participate in the decision, prevents them from making their own decision later. This may be especially important where, as in HD, most at risk adults choose not to be tested, preferring to live in a state of uncertainty. To carry out a test to resolve the anxieties of the parents would then be quite inappropriate. As well as abrogating the child's future autonomy, it also breaches the principle of respect for confidentiality—if tested as an adult, a person has complete control over who else is told about the test result. In addition, there is the possibility that a child's upbringing could be damaged by the result of the genetic testing. Might altered parental expectations of the child's future career prospects, educational attainments or personal relationships be damaging and perhaps self-fulfilling? There is no firm evidence on this point, and it would be difficult to gather "evidence" that would resolve this—what type of evidence would in fact settle this question? So we have strong grounds for caution without the prospect of readily establishing "the truth." Fortunately, most professional bodies and lay disease support groups share this perspective and would not be prepared to carry out predictive tests for HD or similar disorders on healthy children, at least in northwestern Europe and North America. Professionals in other (especially Mediterranean and non-Western) cultures do not all share this perspective, however, and some would be willing to perform predictive tests for HD on even very young children (64). The role of the family in less individualistic societies certainly creates a different context to which we should not transfer our culture-bound judgments without great care, although that does not necessarily mean that our value systems have to be discarded in the face of a traditional medical paternalism just because it is based in a different culture.

Considering the impact of both a disease and information about the risk of disease on the family as a system is helpful in discussing the genetic testing of children (65,66). One major influence on children's responses to a risk of inherited disease is the manner in which they learn about the condition, and whether this happens gradually in childhood or abruptly in adult life (67–71). It is important for families and professionals to consider their decisions over time and not to see the making of a decision as a single event (72).

Carrier testing in childhood is the most hotly contested issue in relation to the genetic testing of children, and both professionals and families differ widely in their approaches (73). Parents of children with autosomal

recessive disorders may wish to know which of their healthy (unaffected) children are genetic carriers. In the context of chromosomal rearrangements, such as balanced translocations, it used to be standard practice to test a whole sibship when the family presented clinically, and a similar approach has been adopted by some pediatricians for Mendelian disorders, notably CF, as molecular testing has become possible. Given that the young children tested for chromosome translocations in the past have not suffered obvious harm, is there any reason why professionals should not comply with parental requests to test young children to determine their carrier status?

One response is to point out that the children themselves will not benefit from the testing until adulthood; the results are not relevant to them until they come to make their own relationship and reproductive decisions in the future. Being identified as a carrier can have effects on an individual's sense of well-being, and we do not know how this could affect a child's developing sense of self. Carrier testing presents the same challenge to the ethical principles of autonomy and confidentiality as does predictive testing, although there will usually be rather less at stake because the child's own health is not in question, but there is still the concern that parental expectations could exert an undue influence on future relationships and reproduction. That may apply particularly in the context of sex-linked disorders or chromosome rearrangements, where the child's own future children may be affected irrespective of the genetic constitution of their partner. There are, therefore, considerations that weigh in favor of deferring a test until the child can participate in the decision (74). Furthermore, performing a test in childhood does not ensure that the results will ever be passed to the child in a comprehensible and relevant fashion in the future, whether the child does or does not turn out to carry the condition. It is the experience of several studies that genetic carrier test results are not always transmitted to the children tested even by the time they are adolescents or young adults, and there are often misunderstandings about the inheritance of the disorder in the family and about the meaning of the test results (75,76). Carrier testing of the young child, then, is not a complete solution to family concerns, and the offer of genetic counseling will often be helpful to the child when older even when the test has been carried out years before.

Discussing these issues with parents who are seeking to have carrier testing for a young child will often lead to an agreement that the family will talk with the child about the genetic issues in the family as he or she grows up. An arrangement can be made with the family either to keep in very occasional contact or to defer future contact until the children decide to seek information and testing for themselves.

It cannot be emphasized too strongly that not testing for a condition is not the same as not talking about it! If

the family has very strong feelings about testing, wanting the test to go ahead when a child is too young to contribute to the discussion, the counselor can prompt a careful discussion of the issues, including the parents' strong feelings, and an exploration of their expectations from the test, but they need not completely block testing if the parents are heavily focused on this. Although it may be appropriate to defer testing to allow some further reflection, a complete refusal to perform carrier tests in young children can lead to anger and resentment that may be very unhelpful in the future. It may be better to avoid rigid positions in such a sensitive area, to advocate caution but then leave the final decision with the parents.

An approach that can be presented to families as often being the best way forward through the tangled issues and feelings may be the encouragement of discussion and openness within a family but the deferral of testing so as deliberately to leave that decision to the child when he or she is older, in adolescence or later. Several studies have suggested that openness about the family's inherited disorder is helpful to the children's future adjustment (68–71). While an imposed solution may result in rejection and defiance, this may help these adolescents and young adults to arrive at reasonable and responsible decisions with which they can live more happily in the future (77–79).

These issues and guiding principles can work out rather differently in the setting of a child being considered for adoption (80). On the one hand, it can be seen as important not to subject a child to genetic testing that would not usually take place if the child had been able to remain in his/her birth family. The idea of testing a child so that he/she can be adopted if the result is favorable and otherwise left in the care system seems repugnant; surely the best adoptive family would be one that is willing to adopt while being aware of the genetic issues and willing to face the possibility that the child may have inherited a genetic problem of some sort. On the other hand, families adopting a child already face numerous uncertainties and the possibility of resolving one of these uncertainties may seem very helpful. In practice, it is usually possible to defer testing and for a serious potential adopting family to meet with the clinical genetics team for discussion. This can be more helpful than simply having a test result and will often lead to their willingness to defer testing until the "usual time."

The final topic to be considered in this section is the handling of requests from a child or adolescent for a predictive or carrier test. The question is whether the legal minor is sufficiently mature to understand the considerations involved in making a decision about testing. Gaining sufficient experience of life to arrive at a wise decision must take time, but it can be argued that living through particular experiences that have given the child an intimate knowledge of the family's genetic disease accelerates this process. Living in a family touched by genetic disease may give a child both the wish to find out

their carrier status and the capacity to make decisions about carrier testing. What might be inappropriate for a minor of the same age in the general population may be very reasonable within a particular family context (81). There are parallels between children being involved in decisions about genetic testing and the involvement of children with short stature in decisions about leg-lengthening surgery (82). It is important to recognize that a child can be involved in a decision without necessarily making the decision alone; children can be brought into the process of making a decision, making a contribution from an earlier stage than has often been appreciated, but this is not an all-or-nothing involvement.

The question as to when children can make their own decisions about genetic testing without parental involvement or even knowledge is separate. An assessment approach has been found helpful in the context of requests from adolescents for predictive testing for HD (83); a similarly careful approach can also be important in counseling young adults as maturity is not attained overnight (84).

### 30.10 POPULATION GENETIC SCREENING

The important differences between clinical genetic services made available to individual families and those provided as screening programs to a whole population have been outlined. There are three ethical aspects to genetic screening programs that need to be considered further here.

First, there is the issue of consent, or, as it is usually known, informed consent. It is always important to ensure that participation in a population screening program is conditional upon consent, but it may be difficult to define "informed consent" so that it can be readily operationalized (i.e. applied in practice in such a way that it can be readily assessed in any evaluation of the screening program: was this particular act of participation in a screening program enacted on the basis of consent, or not? Yes or No?). As a minimum, the potential participant needs to recognize that they have been given a choice and to understand what the choice is about. There may be potential disadvantages to participation as well as potential advantages, and this would have to be recognized. Probably the most serious limitations to informed consent for genetic screening arise from the routinization of the offer of testing—its incorporation into standard clinical practice, perhaps with the subtle discouragement of questioning, and the active promotion of testing by committed and enthusiastic staff.

The second issue to be considered here is the decision-making process whereby any particular screening program is made available to, or provided for, a population. In a national health care system, this will be decided by the health service, at regional or national level. Under a private insurance scheme, such a decision could be

imposed by legislation or determined by commercial factors, the “free” market. What is important from the perspective of ethics is how the decision is made: what evidence is taken into account, being regarded as relevant to the decision? Which interest groups have a say in the decision? On what grounds is the decision made and justified? Are these judgments defensible in open, public debate? This perspective amounts to a procedural ethics, appropriate to the democratic bureaucracies of the early twenty-first century. From this perspective, it becomes especially important to examine the processes by which such decisions are made in practice, as has been done in the case of two genetic screening and testing programs (85,86).

Finally, there is the distinction between maximal and optimal rates of uptake of a screening test. There will often be tension between the conventional goal of maximizing uptake for a screening test that is considered to be “a good thing” and the goal of good clinical practice. A high uptake may be seen as necessary to achieve maximal efficiency both in the clinic and the laboratory, but a very high uptake may be regarded as presumptive evidence of routinization and hence a poor quality of consent. There is certainly no point in using scarce resources to provide a screening test that is not wanted by most members of the public, nor is it adequate to argue that a screening program is worthwhile because it achieves a high rate of uptake. In the context of screening for the health benefit of the individual, it may be assumed that uptake has to be maximized, at least until the marginal cost of promoting further uptake becomes too great, but, especially in the context of reproductive decisions, it may be more helpful to recognize that screening will be valued by some individuals and not by others. It then becomes more appropriate to optimize the uptake of screening rather than maximizing it. This involves making the offer of screening in such a way that those who are likely to find it helpful to participate in screening do so and those who would not find it helpful do not participate. This topic is explored further later.

### 30.11 NEWBORN SCREENING

The first population screening program to be introduced for genetic disease was the newborn screening program for PKU, which transformed the prognosis for affected infants. There is no doubt that this, and the subsequent introduction of screening for congenital hypothyroidism, has been a great success. There is also good evidence that the identification of infants with sickle-cell disease (SCD), and their early prophylactic treatment with penicillin or other antibiotic, is to their benefit. What ethical issues arise in these flagship programs, the “acceptable face” of genetic screening?

First, there is the issue of whether newborn screening for these treatable disorders should be mandatory, as it is in some countries and some states of the United States, or

whether it should be voluntary, on the basis of assumed or explicit parental consent, as elsewhere. The uptake of testing is scarcely influenced in Western countries by legal compulsion—it is universally high—and parental consent must be the preferred route to implementation on all other grounds, so there seems to be little reason to justify compulsion. Operating on a basis of assumed parental consent does not have the explicit advantages of informed parental consent but may be acceptable in this context, where a degree of routinization is likely in practice. If “real” informed consent were preferred, then there would be no basis for the attempt by professionals to persuade reluctant parents to agree to testing for their infants: the parents’ views should be accepted. However, responsible professionals will try to persuade parents to permit screening to go ahead and will regard parental refusal as indicating that the parents have misunderstood the program. In different health care systems, where primary care might be delivered in a fragmented manner by multiple, poorly coordinated providers of variable skill and experience, the case for mandatory newborn screening for treatable disorders would be stronger.

The other issues around newborn screening relate to screening for disorders where the child is unlikely to benefit directly from any clinical intervention. There are reasoned arguments both in favor of and against newborn screening for DMD, for example, and it is not possible to resolve this issue “in principle”; that is, by reflection in the abstract. This is a good example of a situation where practical experience of both systems may be required so that a judgment can be made on the basis of how the two situations differ overall, whether, on balance, screening is worthwhile. For that reason, this is worth discussing at greater length.

There are two principal arguments for screening. First, many families with a boy affected by DMD have noticed a problem in the second or third year of life, but they are usually reassured by friends and professionals, and it may take several more years before a diagnosis is made. The parents in these families are often bitter about the diagnostic delay and the impact this has had on their treatment of the boy’s complaints. They often state that they would like to have known the diagnosis earlier. Second, in some of these families another affected child is born before the elder affected boy has been diagnosed and the family has two (or three) affected sons. If the diagnosis had been made earlier, then the parents could have been offered genetic counseling in advance of another pregnancy, perhaps thereby averting the birth of the second affected child. Although newborn screening would not have the goal of reducing the birth incidence of DMD, it could have a modest effect in this direction.

Arguments against the program include the distress caused to the family when their relationship with the boy is just beginning; it could spoil the first couple of years of the child’s life, and the family’s pleasure in him, without improving the outlook for his health and with

the possibility of damage to parent–child relationships. Practical experience with newborn screening for DMD in Wales, where the program has been running on the basis of informed parental consent for 10 years, has shown that most families are pleased to have the diagnosis early and do use this knowledge in practical planning for the future, including for their reproductive decisions. There has, inevitably, been distress at the diagnosis, but most families have been pleased to know about the condition from this early stage. Parental satisfaction with the diagnostic process, adhering to a protocol refined in the early months of the program, was greater than in a group of families where the diagnosis was made after a clinical presentation with symptoms (87).

Two important issues surround this program: the adequacy of the informed consent process at entry to screening and the adequacy of the support made available to families once an infant has been identified as affected but before clear symptoms, and standard clinical care, are appropriate. First, the uptake rate of >90% suggests an element of routinization, which could undermine the basis of informed consent and would be inappropriate in this disease context. Alterations to the process of testing, marking this test as different from the therapeutically helpful PKU test, reduce uptake to what may be a more appropriate figure of ~70%. This emphasizes the influence of structural and social factors on individual decision making about genetic tests (88). In addition, if infants are going to be diagnosed early then good information, early physiotherapy assessments and some practical and emotional support should be available in addition to genetic counseling services.

Newborn screening for other diseases is feasible, as with CF, SCD and A1ATD, and for many inborn errors of metabolism that can be detected through tandem mass spectrometry (TMS), including medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Which of these tests should be made available? The case for introducing newborn screening for CF is strong in that active management of nutrition and infection can commence earlier after newborn screening, and it is plausible to suggest that this may improve the long-term prognosis, although this has not been proved. Screening for SCD is also of clear benefit to affected infants, so that a program is worthwhile where the disease incidence is more than minimal. Experience with screening for A1ATD is limited, but a program in Sweden was discontinued because it seemed to result in parental distress and increased parental smoking, a specific hazard for affected children.

Considering newborn screening for CF and SCD introduces another issue, that of detecting carriers incidentally but unavoidably through the methods used to detect affected infants. A small number of child carriers of CF are detected because a biochemical test is used to identify those with raised serum trypsin (IRT) levels;

molecular genetic testing performed on those samples then identified the common disease-associated *CFTR* alleles. Those with raised IRT and a single CF-causing allele then have a sweat test performed to see if they are affected or not. Overall, roughly equal numbers of affected infants and carriers are identified (as the program operates in Wales) (89). In contrast, population screening to identify infants affected by SCD identifies all carriers of SCD, not just a small proportion, because the laboratory test identifies all those with sickle hemoglobin (HbS), whether they are homozygous or heterozygous. This is useful in that those compound heterozygotes with HbS and  $\beta$ -thalassemia are recognized but it means that many more carriers than affected infants are detected. This makes more complicated the process of seeking parental consent and may greatly increase the work of community health professionals to inform and support these carriers and perhaps to refer them for genetic counseling. It can also raise questions about the child's paternity.

In relation to metabolic disorders that can be detected by TMS, an important question is whether consent should be obtained for testing each disease individually (with some parents choosing to have screening for some diseases but not for others), or whether consent should be given to “testing by TMS” as a single test, either to be performed or not (this is an instance of the question of “generic” consent, in contrast to specific consent). Because testing for PKU is now performed by TMS, this superficially attractive and simplifying approach to consent would fail to give any real choice about testing children for many of the metabolic disorders for which early diagnosis fails to confer any substantial benefit to the child, and which parents might wish to decline, while accepting the test for PKU. This approach would oblige professionals not to act on indications of a possible problem in some children; this would therefore be unpopular among practitioners.

An example to consider, MCAD is a disease where there can be not only real benefits from screening but also some difficulties. There is still some uncertainty about the natural history of the condition and about the likely balance between the improved prognosis for some of the young children, who are protected from hazardous episodes of metabolic decompensation, and the imposition of unhelpful medicalization on others. Some children who would have suffered no ill effects from the condition itself may be recognized and then admitted to hospital with every minor childhood illness, if their carers lack confidence in recognizing when the child is “sufficiently unwell” to warrant this precaution. Any process of evaluation of such screening programs must be broad based; they must examine not only the clinical medical outcomes but also the social impact on the families caught up in screening and the costs imposed on both the health services and the families involved. The ethical issue in this and some other disorders may

become a practical one—at what threshold of biochemical malfunction should a child be regarded as having a positive screening result—and experience is accumulating to guide practice.

Another important point to note is that clinical diseases must not be subjected to redefinition as cases of mutation in the relevant gene. Thus, in screening for CF, it is important to recall that the aim is to commence early treatment of infants who would otherwise be malnourished or have suffered serious pulmonary infections before the diagnosis was discovered; the goal is not to identify all cases of disease associated with mutations in *CFTR*, including late-onset respiratory problems or male infertility, where diagnosis in early infancy is most unlikely to be helpful. Similarly in MCAD deficiency, if screening is introduced, the goal must be to identify those destined to develop serious problems in early childhood, not all those with mild biochemical abnormalities but without an appreciable risk of severe metabolic decompensation, who would become “patients in waiting” (90). Those involved in making decisions about the implementation of such screening programs must take a broad view and not just reflect a coalition of vested interest groups: enthusiastic professionals, the manufacturers of the technology, and medical administrators interested primarily in containing health care costs.

There are currently discussions about the future shape of newborn screening in many countries. These often focus on the question of which disorders to screen for but, in the United States, there is active debate about broader issues that threaten public acceptance of screening, including the long-term retention of newborn blood spots and their potential forensic use by the state (91). In addition, there are discussions about the acceptability of mounting a newborn screening program to recruit infants to a therapeutic trial (e.g. for spinal muscular atrophy (92)), and there are grounds for doubting the overall wisdom of screening for fragile X syndrome despite some possible advantages (93). Can the advantages be sufficient to outweigh the distressing predictive information for premutation carriers of a risk of midlife neurodegeneration (Fragile X-associated Tremor and Ataxia Syndrome (FXTAS)) or premature menopause and the difficulties of consent and counseling for mildly affected young women?

## 30.12 ANTENATAL SCREENING

There are several issues around antenatal screening, in addition to those discussed earlier about nondirectiveness and screening programs in general. First, there is the question of the goals of antenatal screening. Then there are the unanticipated consequences of screening, especially the impact of antenatal screening on women and couples who become caught up in the clinical process but may not have really thought through the issues in advance. Finally, there is the impact of antenatal

screening on those individuals already affected by the conditions for which screening is made available.

### 30.12.1 Goals

Is the primary purpose of antenatal screening to reduce suffering, to provide choice, or to reduce the costs of health care? Perhaps the best way to address this question is to examine particular screening programs in detail and test out their rhetoric against their operation in practice. If we do that, what might we find? That is the type of empirical ethics research that is needed alongside cost-benefit analyses, which may drive decisions inappropriately if the only evidence drawn upon relates to the economic aspects of screening.

It is almost incontestably good to reduce “suffering,” but whose suffering do we mean? For the present, at least, prenatal screening is essentially targeted at Down syndrome and at structural malformations of the fetus. It utilizes maternal serum screening and fetal ultrasound scans to detect fetuses affected by (or at high risk of) structural malformations and chromosomal anomalies. Fetal anomaly ultrasound scans can reduce perinatal mortality, but most of this effect consists of bringing forward inevitable neonatal deaths so that they are no longer counted in either perinatal or neonatal mortality figures. Such reclassifications of inevitable deaths need not reflect any improvement in the clinical reality for the mother or family, because a midtrimester termination of pregnancy takes the place of a sad but inevitable neonatal death, which might have left the family with fewer regrets, less guilt, and greater emotional support.

Neural tube defects (NTDs) certainly can cause physical suffering in the child, although it may be difficult to argue that anencephaly causes the neonate more suffering than a termination of pregnancy without feticide, but there is no consensus among adults with NTD about the rights and wrongs of selective termination. Many take a “permissive” view, arguing that screening and termination should not be prohibited, but often maintaining that their lives are worthwhile despite their physical problems and that they must be acknowledged and respected as full members of society. There is a strong tension in this position, discussed further later, between the freedom of pregnant women to make their own reproductive decisions on the one hand and the respect due to our fellow human beings, whatever their physical or intellectual capacities, on the other.

Although Down syndrome can cause serious physical problems for affected individuals, it is the intellectual limitations and the stigmatizing physical features that are usually thought of as the major problems it leads to. So the suffering to be avoided through selective terminations of pregnancy is in large part a combination of the sadness likely to be experienced by the parents and the wider family and the social stigma experienced by the affected individual, along with the “courtesy” stigma of those

around him or her, rather than any direct physical suffering. The parents' feelings will be complicated, including sadness and disappointment at the child's physical frailty and health problems and at the limitations imposed on him or her by their genetic constitution, and irrational but often powerful feelings of guilt, of social stigmatization, and of worry about the child's future happiness in society outside the home once the parents are no longer able to care for the child. However, there will often be positive feelings, too. To claim that antenatal screening is motivated by a desire to reduce "suffering" is therefore a complex claim, difficult to justify in any simple and unqualified sense. This claim is made more difficult to accept in practice by the reluctance of many practitioners to accept a mother's decision not to terminate a pregnancy affected by Down syndrome or a similar condition, so that those who decline the offer of pregnancy termination may need real strength to resist the pressure they are placed under and to continue with the pregnancy (94,95).

The offer of informed reproductive choice is also given as a possible goal of prenatal screening (96), but this begs many questions. Given that the imposition of decisions about testing and (dis)continuing wanted pregnancies is burdensome, with its own social and emotional costs, what decision-making task is appropriate to impose on every pregnant woman (97)? Who makes this decision and on what grounds? It is not possible to sustain the view that a simple maximization of the number of decisions made is an end in itself. We must examine the context within which these decisions are made available.

### 30.12.2 Decisions in Social Context

If the termination of a pregnancy on the grounds of fetal Down syndrome is motivated by the desire to avoid suffering, it could be argued that there are alternative approaches to this problem that are often not proposed by public health physicians, health economists, or genetics professionals. These other approaches may have major advantages over the process of prenatal screening and the termination of wanted pregnancies, with the pain and suffering felt by the pregnant woman and the distress, guilt, and depression that so commonly ensue for her and her partner. Society could respond to the challenge of Down syndrome, and mental handicap or intellectual disability more generally, by ensuring that children with such problems are actively welcomed by society and integrated effectively into schooling and work, that parents are provided with a high standard of social support, and that older individuals with Down syndrome are offered well-supported, sheltered housing near the homes of their friends and families. The decisions made about prenatal screening and the termination of pregnancies might be different: (i) if parents were confident that, if their child were to have Down syndrome or a similar condition, neither they nor their child would

experience overt hostility or more subtle forms of stigmatization and (ii) if they could have a realistically optimistic view about the future for their child once they are themselves insolvent, infirm, or dead.

This idyllic state of affairs would require major changes in public attitudes and in the provision of health and social services in most societies, but without such developments any promotion of prenatal screening can be understood as (at least implicitly) coercive. Some families may feel that they have little real choice about prenatal screening because the support they can expect to receive from society for a baby with special problems and needs would simply be inadequate. Altering the social context in this broad way, at the "macro" level, would also be likely to improve "micro" aspects of social functioning, the subtle, intimate hostility that can all too frequently be displayed toward individuals with disability and their parents.

In contemporary society, the notion that "reproductive choice" is a "good thing," good enough to justify the systematic promotion of prenatal genetic screening, is therefore highly questionable. The emphasis on individual choice and autonomy that is so strong in contemporary medical ethics, including ethical discussions of prenatal screening, can be seen as a mirage (98). To consider ethical issues in the abstract, divorced from the social context of those confronting them, is to inhabit a fantasy (99). This is not to argue that individual choice is a "bad thing" or that individuals should be prohibited from using prenatal screening, but the active promotion of screening on the grounds of respecting individual choice is disingenuous if the social framework within which the choice is made available remains unexamined. Such a policy deflects attention away from the processes through which society arrives at decisions about health and social care. These decisions inevitably reflect the interests of different social groups, and to present them as neutral and based solely on objective considerations is actively misleading, making it harder for those with little power and few resources to contribute their views in an effective manner that will be "heard" and acknowledged.

### 30.12.3 Entry to Antenatal Screening

Consent for entry to prenatal screening is often not based on carefully considered and well-informed decision-making, as is known from many studies of the antenatal clinic process and its routinization (100–104). It is perhaps the fetal anomaly scan where "consent" is most problematic in that this is often approached as a happy social occasion rather than a serious search for fetal abnormality (105). Indeed, the way in which the test is offered is often routinized, and this leads to further problems for those women and couples in whom the screening test indicates a possible problem. If they have complied with screening in the expectation that the test will "make sure the baby is alright," such an ambiguous phrase, then

they can find it very difficult when a real or possible problem is identified. Such women can feel swept along on a diagnostic conveyor belt that often leads to amniocentesis and sometimes toward termination of pregnancy; it can be very difficult to slow this process sufficiently to permit reflection or stop the conveyor belt and get off.

Such difficult experiences would be minimized if it were made very clear to all potential screening participants:

- that the primary purpose of screening is to identify pregnancies in which the fetus has a problem, not to provide reassurance or photographs for the baby album or to act as an emotional glue to “promote bonding”;
- that participation is entirely voluntary;
- that professionals are likely to raise the question of terminating the pregnancy if the tests do indicate a problem;
- that the reassurance gained through a normal screening test result is always incomplete;
- that some test results may be of uncertain significance, being neither completely “normal” nor definitely “abnormal,” and these would require further investigation and/or consideration before any decision could be made, but even with further investigation or discussion, confidence in the interpretation of the test results may be impossible;
- that there are services available locally to support families who have a child with Down syndrome, spina bifida, or other conditions likely to be detected by the screening program.

Some pregnancies are terminated in haste when the couple learns about a problem detected on the fetal ultrasound scan or on fetal chromosome analysis, such as a sex chromosome anomaly. Then, when the parents learn more about the diagnosis, especially if the child might have enjoyed a very reasonable quality of life, they can bitterly regret their decision. Such problems are less likely to arise when women are informed about the possibility of “gray” results before deciding to go ahead with screening, but it is emotionally difficult and demanding for both staff and pregnant women to confront these issues in every pregnancy. The issues are therefore often evaded until there is a serious decision to be made in a hurry, and of course these are not the best circumstances in which to make such decisions.

The ethical challenges in this setting are faced by our clients, the society at large, and us professionals. They can be categorized thus:

- Under what circumstances, and with what goals and ethos, are we prepared to make prenatal screening and diagnosis available?
- Pregnant women have to decide whether or not to participate in the prenatal screening programs on offer. Some will wish to take any available measures to avoid having a child with problems, whereas others

will want to welcome their child unconditionally into this world. Yet others may wish to spare their child what they fear might be a life of misery and would prefer to take any suffering upon themselves, suffering the distress of terminating a wanted pregnancy so as to spare their child from physical suffering or from life in a hostile society. These considerations are frequently encountered in families having prenatal diagnosis for a condition they know well, and these circumstances are very different from those that arise in the course of population screening.

- Society has to decide how to support pregnant women and vulnerable children. Should it set out to welcome every infant unconditionally and generate confidence in the willingness of society to care lifelong for those with special needs? Or should it adopt a more hard-nosed, instrumentalist approach to its future citizenry by discouraging the birth of those likely to require more than the average from its health and social services?
- If the system of prenatal screening within which we work is unsatisfactory, to what extent does our compliance with it serve to bolster it and perpetuate these problems?

### 30.12.4 Making Decisions and the Outcomes of Antenatal Screening

Entry to antenatal screening may in practice often be routinized but it is to be hoped that any further decisions, such as whether to accept the offer of an amniocentesis, whether to terminate the pregnancy, will be made consciously and deliberately. Some accounts suggest that, once any screening test gives a positive result, some women feel pressure to take the next step as inevitability. Ethicists sometimes write as if pregnant women should weigh up dispassionately the considerations for or against an invasive test, for or against a termination. They may even propose that there is an ethically correct decision to be made and that they know what it is (106). Research examining the decision-making process suggests that life is more complicated, that women often consider the interests of the fetus alongside those of the family overall (107) and that they usually make decisions in small steps, as they are obliged to, rather than as a grand, strategic plan (108).

It is certainly of crucial ethical importance that our evaluations of prenatal screening programs develop more sophisticated ways of weighing the costs and benefits of screening. At present, it is all too easy for a family tragedy to be recorded, for the purposes of clinical audit or health services research, as the successful identification and termination of an abnormal fetus (e.g. with Turner syndrome). At present, most research and audit on prenatal screening avoids the active search for these sometimes disastrous outcomes, so the evidence base is systematically distorted. This is not merely an issue of

research methodology but a serious ethical issue about the framing of research questions that have received insufficient attention. In this era of “evidence-based medicine,” what types of evidence “count” as such? How are these decisions made?

### 30.12.5 Unanticipated Consequences

Quite apart from the rare miscarriages caused by invasive fetal diagnostic procedures, antenatal screening has other undesirable consequences. One of these is the altered experience of pregnancy known, in the phrase coined by Barbara Katz Rothman, as “the tentative pregnancy” (109); until the antenatal screening results are known, a woman may regard her pregnancy as not really established and not fully (unreservedly) welcomed. This is a different approach to pregnancy that contrasts with the unconditional welcoming of any child born (110). It is this decision, as to when in the pregnancy (or after birth) to welcome the fetus or infant unconditionally, that recognizes the fetus (or infant) as belonging to the human community.

### 30.12.6 Disability Issues, Cost-Benefit Analysis and Sex Selection

The persistent focus of research studies investigating population genetic screening programs on crude cost comparisons, the cost to society of either screening and terminating affected pregnancies or caring for affected individuals, causes great offense to many individuals with disability. It may horrify other citizens, too, but it is especially offensive to those of us who have the conditions that society seems determined to “prevent” on the grounds that affected individuals cost too much to look after. This really does amount to putting a price on a person’s head! Such cost-savings arguments, essentially, that it would be cheaper to stop your patients being born than to look after them, would be totally unacceptable in other medical contexts. Indeed, it is generally accepted that medical care costs money and that society should be prepared to pay for it. The simplistic, narrowly economic approach to prenatal screening reduces human value to a cash price and reflects a deeply amoral cynicism.

There are other reasons why terminations of pregnancy may be justified, but the widespread use of crude cost calculations to justify prenatal screening for Down syndrome suggests that society and the professions have, perhaps by default, decided to promote prenatal screening on those grounds. Such policies have helped to generate considerable hostility toward genetics within the disability movement. This is most unfortunate because genetics may have a lot to offer society, including those with disease and disabilities, and a rejection of genetics *tout court* could obstruct useful progress on several fronts. Such narrowly instrumentalist and simplistically utilitarian attitudes fail to consider the duties we

owe other humans, including our future selves when we become unwell or infirm, and fail to recognize the important virtue of human solidarity.

One obstacle to mutual understanding is that “genetics” covers many different activities. The term can be used to describe prenatal screening programs and their apparent contempt for the worth of people with disabilities. It can also be used to describe research into the causes of disability, which may result in a more sophisticated diagnostic taxonomy and give insights into the causation of progressive and sometimes fatal disorders that cause disabilities; such research may eventually lead to the improved treatment of affected individuals. Hostility to one aspect of genetics may carry over to other areas also labeled as “genetics.” Furthermore, while effective, rational, gene-based treatments, if not gene therapy as such, may be years from widespread application in many areas, even a distant prospect of such therapy generates conflicting emotions within affected individuals and their families. On the one hand there can be surges of hope that individuals already born will be helped by new, rationally designed treatments to lead better (healthier, more able, fuller) lives, while waves of resentment can also arise when anyone suggests that therapy would be wanted; this can be taken to imply a lack of respect for the daily achievements of affected individuals, who live their lives creatively and with enjoyment and who seek recognition as valued individuals, just as everyone strives to do. Neither the (bio)medical model of disability (“you have a problem with your body and we professionals are doing what we can to fix it”) nor the social model (“society is to blame for all the difficulties confronted by individuals with disability”) does full justice to the complex relationship among the elements here (111,112): the cause of a disability, its practical manifestations in the life of an affected person, the broader social impact of their disability, and the emotional consequences for the individual and those around them.

Those with disabilities may fear that genetics will be used by society to eradicate either their disabilities or the people themselves. Of course, the complete eradication of disabilities is never going to be possible because so many acquire disabilities for other (not genetic) reasons, but there may still be great resentment that anyone would wish to do so (113,114). It is likely that for many years it will remain technically much easier to eradicate people with inherited disabilities prenatally, sometimes, and rather inappropriately, regarded as a prevention of the disease, than to prevent the loss of these abilities in those with progressive disorders or to restore them to someone who has lost them or never had them. Suspicion of genetics will therefore persist but it is possible for the disabled and their health professionals to develop a dialog that slowly softens and removes these misunderstandings. This is an important activity from which both groups can learn; the professionals can learn more about the experiences and aspirations of the disabled,

and the disabled can learn that “genetics” is not a single, monolithic entity that aims to wipe them out but refers to a range of different activities, some of which will help at least to understand the causes of inherited disabilities and of progressive, disabling diseases, and may one day provide useful therapies.

One particular disabled community that deserves specific mention here is that of the deaf, especially the Deaf, those with prelingual deafness who use sign language. This group sees itself as a threatened cultural minority, and genetic research into deafness is perceived by some as a direct threat to their continued existence as a distinct minority culture (115). This group of the Deaf often does not see deafness as a problem, in contrast to those with later-onset hearing impairments. Is such prelingual deafness, then, a disease, a disability, a condition, an innocent trait, like red hair, or a marker of belonging to a specific cultural community? They can feel threatened by the twin assault of genetic technologies with the potential for prenatal diagnosis and the treatment of deafness by cochlear implants in infants diagnosed through newborn screening. The source of recruits to the social world of the Deaf may diminish and so the culture may indeed be threatened with extinction.

Mention must also be made of fetal sex selection. Many cultures have a preference for sons; this was true until recently of the ruling and the laboring classes of Western societies. The pressure to have sons has powerful socioeconomic roots and relates to cultural practices such as the dowry and the need for sons to fight, work in the fields, join the family business, or inherit property and names. In some societies, newborn daughters may be exposed or killed. Furthermore, women who have daughters are sometimes abused, assaulted, divorced, or murdered, so that the women can be as eager as their men folk to have a son. In this cultural setting, those who can afford prenatal diagnosis sometimes use it to ensure that a pregnancy does produce a son, especially if they already have a daughter (116). Sex selection, now largely prenatal and based on the social termination of pregnancies in which fetal ultrasound scanning suggests a female fetus, is so common in some areas that the sex ratio in parts of India and China has declined dramatically and is approaching 0.7 female infants per live born male. Indian immigrants to the United States utilize the prenatal sex selection that is legal there, whereas it is illegal in India (117).

Compliance with requests for fetal sex determination as a means to achieve a son can be regarded in the West as collusion with an offensive, patriarchal system that oppresses women and is hugely disrespectful to them. British medicine has decided not to permit prenatal diagnosis for such purposes; to do so would be seen as lending support to an unacceptable system of discrimination. This raises two important questions. First, if a woman seeks fetal sex selection out of fear that she will be assaulted or killed if she has a daughter, then is that

not at least as powerful a justification for prenatal diagnosis and pregnancy termination as many of the “social” terminations carried out every day? Second, if we Western professionals adopt this stance because we hold women in such high esteem, what message is conveyed by our collective willingness to promote prenatal screening for Down syndrome? If the disability movement had a higher profile, would we discontinue that type of prenatal selection, too?

### 30.12.7 The Future of Antenatal Screening

One important technical advance of the last few years is beginning to enter clinical practice. Its impact has so far been modest but it is likely to transform the practice of antenatal screening and prenatal diagnosis, and the associated ethical issues. This is the analysis of free fetal (or embryonic) DNA in the maternal blood, known as *ffDNA*. This is already in widespread use to look for paternally derived alleles of interest (such as the Y chromosome for fetal sexing and the Rhesus antigen for hemolytic disease) but can also be used for prenatal diagnosis for paternally derived autosomal dominant disorders for which the fetus is at risk. These methods allow noninvasive prenatal diagnosis (NIPD) from ~7 weeks of gestation, which will remove the risk of miscarriage from invasive techniques (amniocentesis or chorionic villus biopsy (CVB)), permit definitive diagnostic testing from much earlier in pregnancy than is possible now even with CVB, and shape women’s experience of pregnancies and the place of disability in developed societies (118).

The ability to offer prenatal diagnosis early will be welcomed and will be a great benefit in many circumstances. However, where women currently use the risk of miscarriage to justify their decision not to accept antenatal screening or prenatal diagnosis, they will become less able to resist persuasion or pressure, whether from professionals or family, to accept prenatal screening or, further along the conveyor belt, to terminate the pregnancy. The very advantages of NIPD contain this unlooked-for consequence.

The risk-free availability of fetal DNA from early in pregnancy allows the determination (i.e. the resequencing) of the fetal genome, if the free DNA in the maternal blood is sequenced to sufficient depth (119,120). Less technically complex than this, however, and likely to be realized much sooner in clinical practice and population screening, is the determination of relative dosage of fetal chromosomes allowing the detection of fetal trisomy for chromosomes 13, 18, 21 and the sex chromosomes (and fetal X chromosome monosomy) (121). This opens up the possibility of testing every pregnancy in developed countries for fetal trisomies, with a technology that will before long yield a definitive diagnosis, rather than the relative risk figures generated by current screening methods. This in turn raises some important questions. There is the question of consent for tests whose power is not yet fully

appreciated even by professionals (122); there are also important questions about the prenatal elimination of some major categories of chromosome anomaly, not only the autosomal but also the sex chromosome trisomies and Turner syndrome (123). This major change in the composition of society may be welcomed without reservation by some but will generate both disquiet and frank opposition from others. The advent of next generation sequencing (NGS) in diagnostic laboratories will have many positive uses; the application of NGS to antenatal screening will have important consequences but these have not yet been fully thought through and discussed.

Finally in this section, we should consider the prenatal determination of fetal genome structure (i.e. CNVs) or complete sequence. As in the section on Diagnostic Genetic Testing, we can see that this will present serious challenges for families and professionals. Where there remains a substantial degree of uncertainty about the meaning of WGS results, however, the lack of clarity will be worse because we will not have the phenotype of the child available for direct physical examination or developmental assessment, which simplifies the interpretation of WGS results on a live born child or an adult. Furthermore, there will be major concerns about access to the future child's genome sequence and its interpretation. Will the data and the interpretation be stored? Will the parents be given only the clear items of information about the specific questions being asked in the pregnancy, but not about other health issues, or will the "full" results (as far as that is an intelligible concept) be made available to the parents, even when they have not asked the relevant questions?

### 30.13 CARRIER SCREENING

Screening to identify unaffected, presumably healthy carriers of autosomal recessive diseases in the general population is another form of reproductive genetic screening, and it can be made available to a couple contemplating reproduction, or less ideally in pregnancy, when it may be represented as being "most relevant." Similar issues arise to those in the field of prenatal genetic screening because the simplest outcome measures are the numbers of individuals tested, the number of carriers and of carrier couples identified, the number of pregnancies tested, and the number of affected pregnancies terminated. To attempt simply to maximize any of these figures could lead health professionals to direct their patients into testing, so it is important that health services do not impose crude testing targets that could encourage unacceptably directive clinical practices.

There are potential benefits from being identified as a carrier, especially the ability to make reproductive decisions, such as asking a partner to be tested, but there are disadvantages, too. The negative consequences of being identified as a carrier include the emotional impact of this unwelcome information, the burden of future reproductive decisions, possible lingering concerns about one's

own health and the potential for stigmatization and discrimination in personal relationships. Granted that there will always be many more individuals identified as carriers than there will be carrier couples who could have an affected child, how does one weigh these minor burdens on many people with the more serious positive and negative effects on carrier couples, who will not only be given important personal information but will also have the burden of making decisions about prenatal testing, and perhaps termination, in their pregnancies?

Pilot carrier screening programs for a number of disorders have been set up over the past three decades, especially for CF, the hemoglobin disorders, and Tay-Sachs disease. Such pilot schemes have shown that the general public has little interest in carrier screening but will often comply if screening is actively offered by enthusiastic health professionals (124). Indeed, some studies have shown that the rate of uptake is critically dependent on the way in which testing is made available, varying from <10% to >70%, with higher rates if testing is offered actively and is available on the spot but much lower if a separate appointment is required. It would seem that the mode of offer of the test could be selected to generate whatever rate of uptake of the test was desired. In addition, if screening is made available to women or couples in early pregnancy, then the uptake is substantially higher again (>95%). How is this to be interpreted? Does it indicate a real interest in testing or compliance with an actively promoted test because of the vulnerability of pregnant women to suggestions that they should have a test "to make sure baby is alright?" One's answer to this question may reflect one's attitude to the suggestion that CF carrier screening should be introduced widely into the antenatal setting. If uncomfortable with the policy of the National Institutes of Health (NIH) Consensus Conference, one may well ask, *cui bono*? How was the consensus arrived at? What evidence was considered, and how was it weighed? What (vested) interests were represented or promoted in the decision-making process?

Further issues arise in antenatal carrier screening as to the precise offer to be made—testing just the pregnant woman, or the couple as individuals or the couple as a unit—because the nature of the offer made reflects the goals of the program and will have implications for how these are perceived. What about adding in extra conditions and obtaining generic consent to the whole process rather than to each individual test (125)? What about screening in pregnancy for female carriers of fragile X syndrome, with the problems outlined earlier (126)?

When testing is actively promoted by the dominant social institutions, as with screening for  $\beta$ -thalassaemia in Cyprus, promoted by the Orthodox Church, it can be very difficult for outsiders to distinguish popular consent from institutional coercion. Societies certainly differ in the degree to which individuals are willing to comply with decisions made by authority figures within the family or society at large.

The variation in frequency of autosomal recessive diseases between populations and ethnic groups means that the frequency of the carrier state varies widely. So a carrier screening program that could be appropriate in one population may be inappropriate in another. Problems may arise where racial disharmony and discrimination exist in a mixed population, with two (or more) ethnic groups. The promotion of genetic carrier screening could then be used by one ethnic group to stigmatize and discriminate against the other. This indeed occurred in the 1970s in the United States, when screening for sickle-cell trait (carrier state) was actively promoted and exacerbated discrimination against Afro-Americans in employment. So the social context within which carrier screening is made available can be a highly charged political issue; clinicians and scientists should beware.

The development of new sequencing technologies means that the earlier approach to the introduction of carrier screening, considering one disease at a time, is being superseded by genomic approaches in which carrier status for many recessive disorders is made available simultaneously (i.e. in parallel) as a single investigation (127,128). This is comparable to the introduction of TMS as a screening test for pediatric metabolic disease. In these settings, the process of making a policy decision about the introduction of the test and the information-and-consent process for those being offered the test are both very different when a single investigation gives information about many conditions. The generic nature of the consent is bound to alter the type of discussion that takes place between practitioner and the client or patient (126), although there has been little opportunity yet for experience with this to accumulate. Is it a problem that some may wish to be much more selective about the conditions for which they are screened, only wanting to be given some of the results generated? Or the comprehensive nature of carrier detection may make it seem more worthwhile as a population program, perhaps to be introduced into schools (129). This will be an area to watch in the future to ensure that testing does not become so routinized as to undermine the voluntariness of testing.

In less developed countries, the challenges may be somewhat different as older technologies will continue in use for some years. Once infant mortality rates have improved, so that a country passes through the demographic transition, inherited diseases and congenital malformations become much more apparent, contributing to a higher proportion of the country's mortality and morbidity in childhood. As has been appreciated in some Mediterranean and Middle Eastern countries, the survival of large numbers of children with diseases that can be treated successfully but at a substantial cost raises ethical challenges for a country's health services. As a cohort of survivors appears with  $\beta$ -thalassemia, for example, providing the best current therapy will lead to an ever-growing number of patients requiring

expensive care, in this case, either blood transfusion and iron chelation or bone marrow transplantation. Blood transfusion and iron chelation would then consume an ever-increasing proportion of the resources available for health care and could compromise a country's ability to provide services for many other conditions. Some decades ago, as discussed earlier, Cyprus confronted this by setting up a carrier screening program with the support of the Orthodox Church; this has led to a dramatic decline in the births of affected infants so that the country can afford to care for those individuals who are affected. Several countries in the Middle East (including Iran, Saudi Arabia and Qatar) have their own schemes that encourage carrier screening. Other countries are likely to adopt comparable policies. This raises the question of how active the promotion of carrier screening should be when "too enthusiastic" a program could become coercive, and whether the program should seek to influence the choice of partner (as with premarital screening in a country with arranged marriages) or to promote prenatal diagnosis and the selective termination of affected pregnancies. These are difficult issues that developed countries need not confront in the same way because of their greater ability to afford treatment for those affected. How will the use of carrier screening work out in the context of arranged marriages, in developing or developed countries (130)?

## 30.14 OTHER CHALLENGES IN GENETIC COUNSELING

Several other ethical issues arise in genetic counseling, to which we must refer before passing on to some broader topics.

### 30.14.1 Cross-Cultural Genetic Counseling

**30.14.1.1 Language.** The process of communication in genetic counseling is obviously made much more difficult if the counselor and client do not share a common language in which both can discuss the full range of technical topics and the intimate issues that so frequently also arise. The use of an interpreter may provide a solution but may also generate its own set of problems. If the interpreter is a member of the family, a young child, perhaps, or the male or female partner of the client, then it may be difficult for the client or the counselor to talk freely, and the counselor may lack confidence that the discussion is being reported fairly to the client. Issues of power between husband and wife may intrude, and the counselor may find it difficult to walk the tightrope between collusion with the more powerful partner and causing him (or her) offense, leading to the complete withdrawal of the family from genetic services.

**30.14.1.2 Religion or Culture?** A language barrier is only the most obvious obstacle to communication in genetic counseling. Other cultural issues may arise even

more frequently, although they may not always be recognized as such. Religious beliefs may be given as an explanation by the client to the counselor in accounting for their decision not to make use of genetic testing, especially in the context of prenatal diagnosis and a possible termination of pregnancy. Religious traditions, however, do not always give a clear ruling on the “correct” decision for an adherent to make; differences exist within many traditions on such matters, and it may be the cultural customs and assumptions surrounding a religion that influence client decisions and understandings more than the details of religious doctrine per se. Patients’ and clients’ appeals to “religion” may often be used as a signal by the patient/client that she or he is unwilling to pursue the topic under consideration, having deep-seated objections to the whole process although these objections need not necessarily be theological in nature. This signal is usually respected by professionals in a way that the mere expression of an opinion by the client may not.

**30.14.1.3 Decision Making.** Cross-cultural genetic counseling may also raise the question of different patterns of decision making in families. Who would make the decision about predictive genetic testing for a young adult at risk of HD, for example, or polyposis coli? Would it be the individual at risk, a patriarch or matriarch, or a wider group within the family? When a couple are discussing prenatal diagnosis in a pregnancy, who makes the decisions? (In the United Kingdom, it would usually be the couple making a joint decision but, in the face of a disagreement, it is always the woman who makes the decision). If parents request predictive or carrier testing for a young child, they may assume that they have the right to do that without any need to explain their reasoning to professionals. These “cultural” questions come down to issues of power. To what extent can we Western professionals use our power in the clinical setting to steer family decisions and communication practices, i.e. family power relations, along a path that we find acceptable?

**30.14.1.4 Access.** Access to clinical genetic services within multicultural societies may vary between different communities for a number of reasons, including not only patterns of language use and religion but also broader social and cultural factors. The place of an ethnic minority group in relation to the dominant society may have a crucial role here. Access to all health services may be restricted, and low uptake of genetic services may reflect this as opposed to any specific cultural factor making genetics unacceptable. Access of certain communities in Britain to health care may be restricted not only by the reluctance of women to be seen by male health professionals, or the reluctance of their men folk to permit this, but also by the same influences that restrict uptake of health services by members of the same social class drawn from the dominant (white) majority; these economic and class factors will be especially relevant when recently arrived immigrants are still in the process of establishing themselves economically.

It is important that health professionals do not seize upon either the social or the biological differences between ethnic groups and communities to explain differences in health-related behaviors or in the patterns of disease between the communities without giving very full consideration to other possible factors, such as the material circumstances experienced by the communities. For example, differences in perinatal mortality between groups may reflect differences in socioeconomic class as much as genetic differences or differences in social customs.

#### **30.14.1.5 Customary Consanguineous Marriage.**

Customary consanguineous marriage is especially prevalent in certain South Asian and Middle Eastern groups and may be more pronounced in Britain than is usual in their countries of origin because of the smaller number of potential partners in the relevant community in Britain. Although this does increase the risk of autosomal recessive disorders appearing in children born into these communities (131), it would be all too easy for Western health professionals (or politicians) to attribute blame and responsibility for the disorders to the minority culture and its representatives. Such provocative attributions of blame ignore the stabilizing social functions of consanguinity in many communities, this marriage pattern being widely practiced around the globe, and are not likely to promote any useful mutual understanding or change in customs. High-profile interventions by politicians and public health agencies calling for the communities to end their traditional approach to marriage are likely to antagonize rather than help. If not provoked by such moral assaults, communities that place social value on consanguineous marriages may be able to express concern because of a high perinatal mortality or the frequency of serious genetic problems in young children. It then becomes possible to develop an education program that would be acceptable to the community, and perhaps to incorporate genetic testing as part of an effort to counter the genetic risks of consanguinity (132). Perinatal mortality may also be tackled by attention to maternal nutrition and the provision of effective antenatal care, without an exclusive focus on genetic issues.

**30.14.1.6 Stereotyping.** The final problem of cross-cultural genetic counseling to be mentioned here is that of stereotyping. The counselor must not make assumptions about the likely response of an individual to a genetic problem in their family on the basis of how she or he thinks that a client from that community or ethnic group (or social class) would typically respond. Our inevitably patchy understandings of other cultures could all too easily lead us to imagine a spurious homogeneity within these other communities, especially in the case of disadvantaged ethnic minority groups. There is evidence that health professionals are less likely to offer some services to those from minority groups on the assumption that “they” would not want to consider genetic testing or a termination of pregnancy, falling into this trap of inappropriate

cultural stereotyping. One aspect of the stereotyping is the fatalism that is often expressed by the powerless when facing difficult and distressing circumstances; health professionals should be cautious about accepting it as a complete rejection of western medicine (133).

### 30.14.2 The Naming of Syndromes

Many families arrive in the genetic clinic with the hope that the condition affecting their child will be diagnosed. The process of labeling, however, can have substantial repercussions for the family, which they may not always have foreseen (134).

Where a diagnostic label is available, it may have unforeseen negative as well as positive consequences. Although it may facilitate access to support services, it may also provide an unwelcome insight into the likely future for their child that a family may not be prepared to confront immediately. There may also be problems when a diagnosis is not available, as happens quite frequently. The family may then feel bitter and resentful, especially if the lack of a diagnostic label makes it more difficult for them to access appropriate social, educational, or health services for their child. Where a diagnostic label can be applied, this too may have adverse consequences if educational provision for the child is altered inappropriately—if the child is treated as the diagnosis and not primarily as an individual. There is also much scope for the self-fulfilling prophecies of low expectations on the part of parent or teacher.

A very real problem for some individuals affected by genetic disorders and their families is the name given to their diagnosis, their syndrome. This applies particularly to the field of dysmorphology. It can be difficult enough for a family to accept that one (or more) of them has a disorder manifest in their physical appearance, without insult being added to injury by the offensive nature of the name given to their condition. Although some names are unfortunate but understandable, others are the expression of a brand of medical humor that should not be paraded before the families in our care; this should have no place in clinical practice (135). Given that families now routinely have access to the Internet, they can readily find out all the names given to “their” syndrome, so it is not possible for clinicians to use one name with families and another name for the same condition when talking with their colleagues.

The name “cri du chat” syndrome can be unfortunate when it causes a family to flinch whenever they hear their child’s cry, the cry having caused no concern before they were given the name of the condition. This name was coined in good faith as a clinically useful description and not as a thoughtless witticism, but it does have this unanticipated impact on families. This name, however, need not be used by professionals—5p minus syndrome is a useful alternative—although I suspect that the more evocative name will linger. There are many other syndrome

names, however, especially acronyms, which have surely been devised for their verbal felicity and humorous effect with complete disregard for the impact of the name on those affected and on their families. Examples include CATCH 22 syndrome, LEOPARD syndrome, DEFECT syndrome, and CRASH syndrome. The giving of a name to a syndrome can be as serious a matter as the giving of a diagnostic label to a child.

Another reason for taking great care in the naming of genetic conditions has been explored by Peter Harper in relation to the eponymous Hallervorden–Spatz disease (136). These two research neuropathologists made use of the brains of children with neurological and mental disorders who were exterminated in Nazi death camps as part of the German policy of race hygiene, and Hallervorden (at least) was closely and knowingly involved in selecting children to be murdered so as to provide material for the neuropathology. Harper and others have called for this condition to be given a different name and a preferred term is “pantothenate kinase-associated neurodegeneration (PKAN).”

A final topic to be mentioned under this heading is the process of giving a diagnostic label to a patient or family (137). This process can be very delicate, and information about the diagnosis, even the name itself, may need to be passed slowly to the family as they become ready to accept it. A full and abrupt disclosure of information about a distressing problem in a young child may be unhelpful, especially if the family has not yet recognized the severity of the problem affecting their child, and may block the process of confronting reality. On the other hand, the professional’s fear of triggering a strongly emotional reaction should not prevent them from delivering “bad news” when this is necessary. Professionals should keep their practice in this area under review in a supportive process of group or individual supervision.

### 30.14.3 A Duty to Recontact?

When a family attends genetic counseling, the clinician and counselor provide the best answers they can to the family’s questions. When new information comes to light in the future, especially if it involves treatments or the possibility of prenatal diagnosis, is it reasonable to expect the responsible clinician to recontact the family to pass on this information? If the family is still under review, then no special problem arises, but what if the family has not attended for some years, or follow-up was never planned, or they have changed address? How far does the obligation to recontact such families extend?

A strong duty to recontact could impose such burdens on individual clinicians and counselors, and on clinical genetic services more broadly, that clinical genetics practice could cease to be a viable specialty (138,139). There has to be a balance of responsibility, with the physician updating families with whom he or she has ongoing contact but families being obliged to keep the genetics service

informed of changes of address and to request occasional review consultations if they think that new information may become available that could be of interest to them.

#### 30.14.4 Tensions in Genetic Counseling

At several points in this chapter, I have expressed the notion that there are ethical tensions inherent in genetic counseling practice, such as that between the reproductive autonomy of pregnant women and the support and respect due to individuals with genetic disorders. Another example is that between the “right” of the adult at one in four risk of HD (the grandchild of an affected individual) to find out his genetic status as opposed to the right of his at risk parent not to have his or her genetic status determined. This approach, identifying points of tension where ethical principles may be said to conflict, has both rhetorical and heuristic value and can be most helpful. It has one major drawback, however, in that it suggests that neither pole of the tension is “correct” and that there will be a middle way to be reached by an appropriate compromise. This thought is itself an ethical danger to be avoided; it could lead to a complete ethical paralysis because any position to be advocated could be portrayed as being at one pole of a tension, and the desire for a “middle way” could undermine it. The contemporary, postmodern condition of human life already makes it difficult to sustain and justify any coherent process of ethical reasoning; the use of rhetorical maneuvers to demolish any conclusions emerging from an ethical discussion could easily amount to a form of nihilism.

#### 30.14.5 Pharmacogenetics, Commercialization and the Common, Complex Diseases

The promise of “the new genetics” is that an improved understanding of the genetic basis of the major diseases of Western society will give new insights into their pathogenesis; this, in turn, will lead to improved, indeed truly rational, therapies. From an understanding of the contribution of genetic variation to disease susceptibility, it will be possible, so goes the implicit promise, to calculate each individual’s personal profile of disease susceptibilities and hence define a suitable set of lifestyle measures, nutritional recommendations or preventive medications that will keep the individual in the best possible health. This goal sounds laudable but, as soon as it is examined closely, numerous difficulties and objections appear.

First, there are problems with gathering and analyzing the data that would be required to dissect the genetic basis of the common, complex diseases such as diabetes, hypertension, rheumatoid disease, osteoporosis, cerebrovascular disease, coronary artery disease, Alzheimer disease, and the common cancers. Working with genome-wide panels of SNPs in linkage studies, it has proved possible to define many of the gene loci important in a small subset

of those affected by such conditions, the 5% or so of cases where there is an effectively Mendelian predisposition to disease, but there has been much less progress through GWAS toward defining the risk-modifying genetic factors of lesser effect. For most complex conditions, only 10–20% of the genetic contribution to risk of disease has been assigned. Given the realities of human population history, the nonrandom association of specific sequences with each other and with disease may result from the operation of several different factors other than simple linear processes of disease causation. This has (predictably (140)) made it highly problematic to establish the causal nature of any associations that are identified, even if they have been replicated in independent studies. Not only are there problems of linkage disequilibrium but also the nonrandom mating of humans throughout their history and prehistory for both geographical and cultural reasons, the varied and fluctuating nature of selective processes, and the present rapid mixing of populations, conspire to make it immensely difficult to assess the influence of specific “genetic backgrounds.” The dissection of quantitative trait loci in the mouse has only been possible because of the imposed pattern of breeding of defined laboratory strains and the close control of environmental variables. The feasibility of either collecting sufficient human data or conducting an interpretable analysis capable of identifying disease-related polygenic (small effect) molecular variation is poor. While the problems of linkage disequilibrium, using SNPs as proxies for the true causal factors, will diminish as more complete human genome sequence data accumulate, the problems of analysis will remain and even become more difficult as the mass of data in need of interpretation increases dramatically.

Second, where molecular variation associated causally with disease susceptibility is identified, it still might not be amenable to effective therapeutic intervention. In the context of genetic disorders, there has been a long lag period between improved understanding of pathogenesis and improved treatments for patients. It would be irresponsible to raise public expectations beyond the point where we can be confident that progress in knowledge will lead to progress in therapy.

Third, there has been a strong temptation for commercial laboratories to make available, to sell, molecular genetic testing for disease susceptibility, no matter how poor the evidence base. Indeed, several providers of such SNP panels have achieved high visibility on the Internet. The principal weakness is that the SNPs tested account for such a small proportion of the causal factors, while the marketing of the tests often claims, misleadingly but sometimes only implicitly, that they can be used to guide health-related decisions. Such claims are especially worrying if someone with a significant family history of disease relies on such tests instead of seeking a formal clinical genetics assessment and mutation testing in any relevant Mendelian genes. The legal status of such GWAS-based SNP tests has been under review in

the United States and several companies have recently ceased these activities. There have also been discussions in European countries about the need for regulation of this “direct-to-consumer” marketing of genetic tests.

For the present, the use of GWAS-based risk estimates for cardiovascular disease is no improvement on measuring blood pressure and cholesterol and using standard clinical scores (141,142).

Another set of concerns about genetic testing for disease susceptibility relates to the behavioral responses to risk information. Although the rhetoric emphasizes the positive behavioral application of risk information, experience so far does not suggest that it works out that way (143,144).

- It could cause great stress and anxiety, through identifying those at increased risk of disease without offering adequate countermeasures.
- It could consume limited health care resources without improving health.
- It could lead those given increased risks of disease to place inappropriate demands for intervention upon their regular health care providers, posing a threat to these systems.
- It could distract attention from environmental and lifestyle measures that are already known to be helpful to the whole population (the shaping of national food, employment, education, transport, and leisure policies to promote healthy eating and exercise).
- It could distract attention from the group of individuals at very substantially increased risk of disease, for whom more effective interventions are appropriate and already available (e.g. LDL-receptor disorders, Lynch syndrome, etc.).
- It could lead to paradoxical behavioral consequences for those at high and at low risk of disease, through inducing a sense of either fatalistic inevitability or inappropriate invulnerability.

An adequate evaluation of any screening test for susceptibility would include assessments of the clinical, psychological, social, and economic consequences of introducing the test, for those given decreased as well as increased risks, and for society as a whole. There will be a temptation to examine only the clinical consequences for those at high risk of disease, and this would be much too narrow an assessment. A full evaluation should preferably be conducted before any such disease susceptibility screening test could be introduced to either a state or a private medical care system. Where both types of systems operate, applying restrictions to the state health care but not the private system could undermine the effectiveness of the state system, where such testing does turn out to have a useful clinical role. There is a danger that restrictions on the introduction of clinically helpful susceptibility tests could be exploited as a means of limiting pressures on the health care budget, using appeals to “evidence-based medicine” as a veil.

Perhaps the single most important ethical issue in relation to population screening for susceptibility to disease is the nature of the evidence that would be required to justify and permit screening of this type. Crucially, what evidence would be required and who makes that decision (145–148)?

Although there are clearly many potential problems with genetic susceptibility screening, not all of which have been discussed here, it must not be forgotten that there have been useful outcomes of genetic research in the area of the complex disorders through GWAS, principally in opening up an understanding of disease mechanisms rather than any established clinical utility from risk stratification. Such insights may lead over time to the development of radically new therapeutic approaches, although it will be many years before any such therapy could be validated for general clinical application. More likely in the short term, however, and certainly more likely to reach fruition in the short-to-medium term, is the possible use of genetic tests to guide pharmacological therapy. There are several important clinical entities that may represent a common end point of rather different pathogenic processes, including hypertension, depression, and seizures. It is widely recognized that the selection of the most appropriate therapy for patients with these problems is immensely difficult and is currently a fairly hit-and-miss affair. At present, all affected individuals are lumped together for therapeutic trials, which then recognize the medicines most effective in the majority of patients. What might become possible is the selection of the most appropriate therapy for each individual, given the pattern of molecular genetic variation (i) that has predisposed them to develop the disorder or (ii) that influences their likely response to a range of different therapies. This tailoring of the treatment to the individual represents the Holy Grail of therapeutics. We must not expect such developments to work out quickly, because the complexities of human biology may simply make this goal unattainable, but it is reasonable to entertain the modest hope that progress in this direction will accumulate over the next few decades. While cautious hope is appropriate, promoting exaggerated expectations will not be helpful and could be damaging.

Another possible benefit of identifying genetic variation associated with disease susceptibility, where this becomes feasible, could be its application to clinical trials of new therapies. If only those at increased risk of a disease are recruited, it may require fewer trial participants to be followed for fewer years before an effect of the therapy should be apparent. A possible problem here is that this high-risk subgroup, while important in its own right, may not respond to therapies or preventive measures in the same way as the rest of the population, so extrapolation from them may be problematic. Studies correlating DNA sequence variation with adverse drug reactions are also planned and would be an appropriate use of the

technology. If individuals susceptible to adverse drug reactions could be identified, then their suffering and the substantial health care costs associated with iatrogenic disease could both be reduced.

### 30.15 RESEARCH IN HUMAN GENETICS

The principal issues to be considered are consent, confidentiality, and control over the process and application of the research. The safety of gene-based therapies is not yet a major issue as there have been few trials of gene therapies and these early trials have been handled with care through conventional safety assessment routes. The few casualties have resulted from either unfortunate effects of the proposed therapeutic agent or from poor compliance with procedures. We will also consider questions relating to the study of human diversity and “race.”

#### 30.15.1 Consent and Feedback

At recruitment into a research project, it is important that participants appreciate that the genetic sample being obtained for study is going to be examined in a research laboratory—the analytic process may not be subjected to the same quality control measures as in a regular diagnostic laboratory, and the applicability of the results to any health care decisions may not have been established. It may be the simplest and cause the least confusion if the research studies are thoroughly separated from the clinical services being provided to the patient (149), although this is not always feasible. It is obligatory, however, to make clear to the participant who is also a patient how, if at all, the research results may alter their prognosis or treatment. If participation will make no difference to their condition or if the results will not be revealed to the participant, then this must be clear at the point of recruitment to the study.

With banked samples of DNA or tissue, it is seen as good practice to return to the sample donor for consent to carry out new investigations for which specific consent had not previously been obtained (150–152). This also allows the donor to be given fresh information about the progress of the research. If the donor has died, then it might be appropriate to contact his or her family if information to be generated in the research could have implications for them. Such recommendations for the practice of research are often feasible in relation to uncommon disorders, such as malformations or Mendelian diseases, where small numbers of patients or families are involved and the research team may have a continuing relationship with the participants. In the context of the common, complex diseases, however, where data on large numbers of individuals are being examined, the imposition of these requirements may make it impractical for some types of research (e.g. genetic epidemiology) to proceed at all.

With banked tissue samples that were obtained for diagnostic purposes, perhaps at surgery for the removal

of a malignancy, and for which consent for research was not obtained, should researchers have to contact the patient and gain their consent before carrying out the research? Surely yes, if the investigation might generate clinically important information about the patient’s genetic constitution, but otherwise perhaps no, if the research is only intended to characterize the tumor tissue. If the patient has died, should the family be asked to give consent before the researchers proceed with their studies? Again, yes, if the results could be relevant to other members of the family, but perhaps no if the study is essentially epidemiological with no direct consequences for family members.

It is important to distinguish on the one hand between research investigations carried out on individuals or groups of individuals who have a specific genetic condition or disease, such as a Mendelian or chromosomal disorder, and on the other hand those studies of large groups or populations that seek to identify the genetic influences upon the more complex, multifactorial disorders. These population studies either seek to correlate clinical information available at the time of the genetic sample collection with genotypic data generated in the study or continue to gather clinical information about those who have contributed samples to compare susceptibilities to disease and responses to treatment that become apparent over time. There are very substantial differences between these types of research that must be made clear to participants at recruitment.

When molecular genetic studies are carried out on individuals with Mendelian or chromosomal disorders, this will generate information about the underlying basis of their condition and may provide insight into the pathogenesis or prognosis of their disorder. Although such information should not be used as an inducement to persuade individuals to contribute to research, it may be made available within a suitable clinical framework if that is the wish of the participants. In some studies, this may be inappropriate but it will often be thoroughly reasonable to provide feedback from the study to participants. In population-based research, however, this is much more problematic.

In studies seeking associations between the common, complex diseases and individuals’ genotypes, the research, if successful, could provide information that would be relevant to third parties such as insurers or employers as well as to the individuals and their families. This would need to be explained in counseling before recruitment unless either the samples and the relevant clinical information were anonymized or the results of the analysis were provided to participants in the form of general conclusions and not as the particular results applicable to each individual. It is of course impossible to provide individual results when anonymization of the samples and their accompanying clinical information has taken place, but anonymization cannot be performed when clinical information is to be gathered prospectively

for use in the analysis. There are good grounds for avoiding the feedback to individual participants in this type of research of their personal results, however, even when it would be a possibility.

First, agreement in advance to the principle of being given individual research results at the end of the project will usually be invalid, because the nature of the results will usually not be at all clear at recruitment. If feedback is left to the discretion of the researchers, when they consider the results to be “relevant” or “important” for the individual, then the inevitable enthusiasm of the researcher is likely to exaggerate the weight of the findings. It would be far more appropriate for the ethics committee approving each population study of a complex disorder to expect the researchers to feed the general results of the study back to participants but not to provide individual results. Interested research participants could then seek appropriate counseling and testing (i.e. effectively retesting) in a clinical environment if they so chose, if and when the study results were validated and an accredited diagnostic laboratory were able to conduct the analysis. In this model, participants in anonymized studies would have the same access to the research findings as participants in the studies with ongoing collection of clinical data.

In recruitment to open-ended research, whose future uses cannot be predicted, it may be more important to provide assurances that future investigations will be subject to independent ethics review than requiring researchers to recontact participants to approve each proposed new analysis. The early issues raised by “gene databanks,” especially the instructional problems of the Icelandic deCode databank (153,154), have evolved as the focus is moving toward assuring proper process rather than explicit consent for each application of the sample or data. As it becomes more difficult to guarantee complete privacy, which occurs as greater quantities of genome sequence data are produced and released, it may be misleading to guarantee privacy but instead the need is to focus on clarity (transparency) about this along with ensuring independent ethics review of new projects and the prevention of genetic discrimination on the basis of any information that is released or reconstituted inappropriately (155–157). This accords well with the perspective of Manson and O’Neill (158).

“Informed consent” as a concept has been asked to carry such a weight of responsibility that informed consent as an interactional process in the clinic cannot support it (159). At times, this has to be put to one side if important research is to be feasible (e.g. some types of newborn screening research (160)). On other occasions, informed consent may need to be modified (“tailored”) to make it useful in practice as well as in theory (161).

There are additional ethical problems with obtaining consent for the recruitment of children or incompetent adults (162). Although parents can give valid consent for the recruitment of their children to research, research

should in general not be performed on children where it could be conducted adequately on adults. Furthermore, children should be involved in discussions about research to the extent that they can understand the issues and contribute their views. If children withdraw their assent for research, then this must be respected, whereas, in contrast, important therapies may be administered against a young child’s wishes as long as the parent consents. Particular concerns might be raised by research into the predictive testing of children for later onset (usually adult-onset) disease for which no useful health intervention is available in childhood. Similar concerns apply to newborn screening programs where the natural history of the disorder is unclear, or where the purpose of recognizing a high-risk subgroup of children would be to recruit them into a trial of possible preventive strategies (e.g. for juvenile-onset diabetes mellitus). In such a case, the goal of recruitment into a trial must be transparent to the consenting parents at the point of entry; otherwise they could agree to participate in screening on the assumption that it would benefit their child and then find that there was no established treatment for a child shown to be at risk.

The important considerations relating to the recruitment of incompetent adults into research are not specific to genetics research and will be passed over here, suffice it to say that any decisions made must take the subject’s best interests into account and must not be enforced against their will (i.e. at least the passive assent of the subject is required). The context is very similar to conducting diagnostic investigations on an incompetent adult at the request of a concerned relative, anxious to know if they might have a child affected by the same (so far undiagnosed) disorder.

### 30.15.2 Confidentiality

Medical, personal, and demographic information contributed to a research project must of course be kept securely, as for their medical records, and the privacy of research participants must be protected. Third parties should not be given personal genetic information about individuals without their specific consent. In studies where the samples and data are anonymized, the protection of genetic privacy is simpler, but elaborate precautions, including encryption and tightly restricted access, may be needed to ensure the confidentiality of subjects in population studies with continuing data collection.

There is pressure from research funders to obtain the maximum benefit from the research undertaken and this has led some funders to insist that raw data be made available at the end of a project for other researchers to analyze. This carries dangers in that the identity of individual research participants could become known and their very personal genome sequence data might in effect become public. In addition, the practical burdens that this policy of the NIH imposes upon researchers from outside

the United States are such that it may in practice restrict research collaboration instead of opening it up (163).

The attachment of research results to patients' medical records without their knowledge is a potentially serious problem, and this danger is one of the reasons for the recommendation that genetic research should be carried out in a different laboratory, and the results recorded in a separate format, to be kept distinct from the individual's regular medical records. Otherwise, a member of staff unaware of the background context could inadvertently pass on research results that are highly sensitive or of uncertain significance, or where the participant had chosen not to be told, or staff could act on the results in a clinically inappropriate fashion.

### 30.15.3 Control and Ownership

In most jurisdictions, patients who have donated a sample of blood or tissue for research, or who have had blood or tissue removed as part of their medical care, thereby lose rights in that tissue. Ownership passes to the relevant clinical or research institution. This used not to cause many difficulties but the commercialization of biotechnology and of biomedical research, with potentially large sums accruing to researchers developing the right molecular technologies, to their institutions, and to their investors, has partially undermined the former "gift relationship," which (in many countries) used to motivate patients and members of the public to give blood and tissue samples for research, much as for blood transfusion services. Although individual patients and research subjects are expected to treat their genetic material as a part of their person, and therefore not a commercial resource to be bought, sold, or otherwise exploited, the very same genetic material can be treated as property by researchers, institutions, and corporations. This contrast is explicit in many of the research consent forms used in genetics research, in which patients contributing samples have to sign away any right to commercial exploitation or benefit with respect to the sample before it will be accepted into research.

Patients and clinicians will generally acknowledge that the practical, clinical application of advances in human molecular genetics to the welfare of individuals with genetic and other diseases requires financial investment and therefore the involvement of biotechnology and pharmaceutical corporations. Many, however, feel revulsion at the way this is working in practice to the advantage of corporations or laboratories that have contributed only to the very last stage of an arduous struggle to identify the genetic basis of the relevant diseases. It offends the sense of justice of many individuals that patients and families with genetic disorders, who have contributed biological samples to research and often also supported the research by fundraising activities over many years, now find that they, or the health services that care for them, are being charged

license fees for applying the discoveries that "their" research led to.

The question of whether human (or any other organism's) DNA sequences can be patented has roused similar passions. Patenting in general is conditional upon three criteria: novelty, an inventive step, and an industrial application. Discoveries, therefore, should be clearly distinct from inventions, and so naturally occurring DNA sequences, genes, and organisms would seem not to be patentable, but patents that give effective control over certain genetic sequences have been awarded. A landmark legal decision was the granting of a patent on a modified organism, an oil-eating bacterium, by the US Supreme Court in 1980, following which precedent further patents on organisms and DNA sequences have been granted. This heralded, perhaps enabled, the spate of investment in medical biotechnology over the past few decades (164). A rush for patents on sequences of human DNA led to competition between research groups eager to patent specific disease genes and to the race between the public and private human genome sequencing projects. The debates about patenting human gene sequences continue within the United States and internationally.

Openness and a collaborative approach among scientists would be preferable to commercial secrecy on any acceptable understanding of the scientific endeavor, even if this would entail slower progress in understanding the mechanisms of the human genome. It seems likely that commercial secrecy has distorted the process of research and has perhaps slowed the overall pace of scientific progress in this field. Whether a more collaborative spirit can be reestablished in the next phase of research is uncertain but this must be an important goal for scientists concerned for the ethical conduct of their craft.

### 30.15.4 Human Genome Diversity Project, Human (Pre)History, "Race," Community Consent, and Sharing of Benefits

One area of human biology that is being illuminated by genetic research is that of the history of human populations. By defining the human genetic variation present in populations around the globe, the movement of peoples over the millennia may be traced and compared with the understandings reached in folklore and through other tools such as archeology and comparative linguistics. The making of artifacts and the speaking of languages, however, can be learned, can be transmitted culturally, so that a comparison of the spread of a style of pottery across Europe with molecular data from surviving populations may give an indication of the extent to which the spread of the artifacts reflected the movement of people and how much resulted from the social learning of new customs. One could even imagine tackling classical myths, such as those of the Aeneid: Do modern Romans have Trojan Y chromosomes but Sabine mitochondria?

What problems lurk in this apparently delightful backwater of molecular archeology? One issue is the potential misapplication of molecular results to make “race” a superficially more valid concept. Although human populations differ in their physical characteristics and their genetic constitutions, there is no clear demarcation between population groups. We belong to communities socially, but these communities are not biologically distinct entities that correlate with specific genetic differences at the level of the individual. Population genetics describes the variation in gene frequencies between groups in a statistical manner, and its application to individuals is fraught with scientific problems as well as cultural confusion. Even the drawing of geographical boundaries around populations is arbitrary, likely to misrepresent a cline in gene frequency as a biological discontinuity when the mean frequencies of specific genetic variants in the two constructed groups are found to differ. That is why the term “race” has been discredited in the biological sense, and the term “ethnicity,” indicating a social group to which an individual chooses to be affiliated, is used instead in the social sciences.

We must remember that social tensions between ethnic groups, sometimes associated with real differences in biological characteristics, have always been used to justify discrimination against minorities and against neighboring communities or countries. Although scientists may have no such intentions, there is every possibility that genetic studies that focus on the differences between population groups will be systematically misused. Molecular reconstructions of population history are likely to support some popular or traditional “origin myths” and to disconfirm others. How might such evidence be used by those antagonistic to their neighbors? If the myth of a group’s distinct origin is supported by a research finding, then discrimination against that group, where it is in the minority, may be strengthened. Where a research finding disputes the oral or written tradition, the group may be subject to mockery or abuse. However fascinating, we must be very cautious in pursuing such studies without the full involvement of the groups concerned. Fortunately, the HapMap project seems to have learned from earlier projects and has largely avoided these problems (165–167).

The potential application of samples and results from the human genome diversity project to other fields, especially those relating to socially important characteristics, such as intelligence or other valued traits, raises the frightening prospect of major social conflicts and political disputes. If a site of genetic variation, such as a SNP, were found to be correlated with variation in IQ in one population, the frequencies of these SNP alleles would be assessed in other populations and spurious claims could easily be made about differences between the populations in IQ. The “Race and Intelligence” debates of the 1970s would appear tame in comparison with what could emerge. There are many problems that can be foreseen as likely consequences of such research, including

an increased emphasis on nationalism in politics, higher levels of interethnic conflict within multicultural societies, and a greater reluctance of the public or the state to support special educational interventions for children from disadvantaged ethnic minority groups. To pursue the research without attending to the likely social consequences would be irresponsible (168), and there seems to be no prospect of neutralizing the potential disasters.

One issue that has attracted much discussion is the process through which valid consent for participation in this research could be gained. When dealing with indigenous, aboriginal communities who have had little exposure to external influences, and no science education, it may be effectively impossible for the research team to educate each member of the community to the same understanding of the project and of their rights as in genetics research conducted within a Western society. Is there a place for a different type of consent in this setting? Can a community give its consent to participate, through its own processes of discussion, in the light of information from, and discussions with, project representatives? Does each individual still need to give their personal consent, and what would that mean in societies with little concept of individual autonomy (169,170)? Furthermore, is there a place for community inducements to participate in research, such as genetic testing for a prevalent disease, or provision of medical care for a defined period, or would that be improper leverage? What if the project were to identify some important disease resistance factor, which could yield enormous profits when commercially exploited—(how) would the community benefit from this in practice?

### 30.16 GENETICS, GENETICIZATION AND SOCIETY

Genetics has received increasing levels of public attention since the start of the Human Genome Project in 1990, and this trend seems set to continue as more findings emerge. Although gratifying to geneticists, there are problems with this focus on genetics, especially when society looks to genetics to explain, and even perhaps intervene to “solve,” social problems. The list of social problems for which a gene is being sought now is long and strikingly similar to the list of social vices that concerned the eugenics movement 70–120 years ago. The list of traits of interest, or concern, to the traditional eugenicists included homelessness, addiction to drugs and alcohol, learning difficulties, sexual orientation, violence, impulsivity, and criminality.

When the phrase “gene for X” is translated into something like scientific language, then the absurdity of some of the public expectations becomes clear. This phrase becomes “a site in the genome, not necessarily a gene, at which DNA sequence variation is associated with variation in the propensity to develop X as a problem, although this association need not be causal and

may only be found in one or a few population groups.” The links mediating the social consequences of genetic variation are so long and so complex that, even in principle, it could never be possible to predict these consequences from the molecular facts, proceeding from the DNA sequence through cell biology to neuronal excitation and then the behavioral phenotype in its full social context. The genetic sites at which molecular variation correlates with behavioral consequences, for example, will not be genes “for” the social problems. Rather, the genes will have distinct biological functions that evolved over millennia and that may be elucidated by the relevant neurosciences. The brain is far too complex an organ for geneticists to be able to make detailed predictions about behavior, although certain statistical associations between molecular variation and the probabilities of specific behaviors may be established.

The legal system is one arena in which disputes about the contribution of genetics to behavior may well be argued out in the future. Leaving aside the biological validity of claims that a crime was committed “because” the guilty individual was predisposed to this action by his genetic constitution, there are two possible responses to this claim: either the genetic predisposition can count in mitigation because the person’s responsibility was indeed limited or the likelihood that the criminal will reoffend should ensure a heavier sentence than usual, perhaps even an indefinite sentence, and perhaps even in advance of any specific crime, a form of “preventive detention.” A case can be made for both arguments, and the legal consequences of following either course would be hugely disruptive. Legal systems might be best advised to ignore the evidence presented of a genetic predisposition to criminal behavior except in the most unusual circumstances.

Genetic determinism is the attempt to reduce the whole of biology to the physical sciences, with the behavior of organisms being shaped largely by their genetic constitution. This is a powerful but destructive concept and in reality is a doomed enterprise. Given the inevitable limitations of the physical sciences in dissecting the functions of the brain, and *a fortiori* our limitations in tackling societal characteristics and problems, how should clinical geneticists respond to the widespread misunderstandings about the relevance of genetics to social issues?

- We should ensure that we do not inadvertently exacerbate these misunderstandings through the inappropriate use of pseudoscientific terminology—“genes for X.”
- We should dissociate ourselves from, and refuse to participate in, research predicated upon such misleading premises or likely to promote such misunderstandings.
- We should speak out, as individuals or, preferably, collectively, when we see genetics being hijacked and abused by those with damaging social or political motivations, especially if we see that vulnerable and

inarticulate groups of our patients are likely to suffer as a result.

- We should take care not to attribute health problems to genetic causes when social and political factors are likely to be as heavily involved and probably more open to remedy. This could, of course, be to our professional disadvantage, because we might benefit from research funds if the principal cause of a problem is seen as being largely genetic, but that would be intellectually dishonest and would, eventually, return to haunt us as our failure to resolve the problem was recognized.
- We should combat inappropriate talk about genetics to help minimize the harm done to the families in our care by some of the wildly exaggerated expectations current in the media.

The tendency to attribute causation of health or social problems to genetic factors is an example of “geneticization,” a term coined by Abby Lippman to describe the more general practice of accounting for observed differences between individuals and populations in terms of underlying genetic differences (171). This process allows vested political interests to obscure the remediable, environmental causes of social inequalities in health and individual attainment by focusing attention on the fixed and unalterable genetic constitutions of individuals. This, of course, fits well with the conservative view of human nature as often propagated under the label of sociobiology or evolutionary psychology; from such a perspective, social problems are framed as biological inevitabilities determined by each individual’s genetic constitution. This can lead those frustrated by the problems they see in society to advocate technological solutions when collective political action may be much more appropriate and effective. The process of geneticization therefore distracts energy and resources from the social and environmental strategies that could lead to real solutions.

One aspect of genetics research that is especially alarming, because of the ease with which it could be misapplied, especially in the context of “race” and human diversity, is the genetic dissection of nondisease traits, particularly intelligence and personality traits, and including variation in intelligence within the normal range. The apparent rationale for pursuing this research is that it may teach us about mild learning difficulties and about fundamental brain processes involved in learning. Given the barriers to interpreting any associations that may be found between intelligence and molecular variation, however, I would argue that the short-term results of such research are more likely to be social mayhem than a productive understanding of cognitive processes. The results are likely to be distorted, deliberately, by those intent on mobilizing political support behind racist or nationalist campaigns.

One final topic to consider here is the “thrifty gene hypothesis,” as an example of geneticization distorting

the research agenda. This hypothesis was proposed by James Neel to account for the high frequency of type 2 diabetes mellitus in aboriginal societies undergoing rapid development. A “diabetogenic” genotype would be favored as promoting maximal efficiency in food use when food supply is limited. When food becomes abundant, the efficient use of food becomes unnecessary and perhaps a disadvantage, with type 2 diabetes (T2D) developing as a consequence. On this understanding, T2D will remain prevalent in societies emerging from a harsh subsistence because of their genetic constitution, which will change over some generations as new selective forces operate. The emergence of this hypothesis gave an apparently adequate account for the very high frequencies of T2D found in some aboriginal communities; other possible causal factors, including socioeconomic factors, received little attention.

Research within a different paradigm has shown that the risk of developing T2D (and other chronic diseases) in adult life is greater for infants born with fetal growth retardation. This research has supported other hypotheses: either “fetal programming” (172) or perhaps the common, genetic basis of both fetal growth retardation and a propensity to T2D (173). The fetus may be programmed by the intrauterine environment to respond throughout postnatal life to nourishment and other environmental factors in a manner reflecting its growth in utero—the Barker hypothesis of the fetal origins of adult cardiovascular and related morbidity. This challenges the thrifty gene hypothesis, although both explanations could have some validity, and an extreme fetal programming model that discounts genetic factors is untenable. Given this, how should we respond to evidence that the incidence of T2D in some aboriginal populations is falling faster than would be expected by selection against a genetic predisposition to diabetes? Public health officials should be delighted, because the postwar improvement in fetal and infant nutrition may now be taking effect, supporting the fetal programming hypothesis. There would be every reason then to hope that attention to the nutrition and general health of the young aboriginal women should reduce this epidemic further in future generations.

With hindsight, it can be appreciated that the genetic explanation for an epidemic of morbidity in a deprived ethnic minority population led health professionals to discount further efforts at preventing T2D by attention to environmental measures. With hindsight, we can see that public health would have been better served by appropriate efforts in nutrition and antenatal care (172) and perhaps by more general attention to deprivation and social status (174).

### 30.17 REPRODUCTIVE TECHNOLOGIES AND CLONING: “REPROGENETICS”

Three reproductive technologies need to be discussed here. These are preimplantation genetic diagnosis (PGD),

human reproductive cloning, and NIPD by the sequencing of free fetal DNA (ffDNA) in maternal plasma.

PGD entails all the procedures of in vitro fertilization (IVF)—superovulation, oocyte harvesting and sperm collection—as in the treatment of infertility, along with the strict obligation to use reliable contraception alongside the IVF procedures. The zygotes are allowed to develop to six to eight cells, when one or two cells are removed from each morula for analysis, employing either fluorescent in situ hybridization (FISH) techniques, to look for chromosome anomalies or microdeletions, or polymerase chain reaction (PCR) methods, to identify specific disease-associated mutations or the number of repeat units in a triplet repeat or a microsatellite sequence. Then, an embryo (or perhaps two) without evidence of the family’s genetic disorder is implanted into the woman’s hormonally prepared uterus.

PGD can be the perfect solution for couples with infertility who also have a risk of transmitting a serious genetic disorder to any child they might have. For couples without a fertility problem, but who are concerned about transmitting their genetic disorder to a child and who wish to avoid the procedures of prenatal diagnosis and pregnancy termination, PGD may also appear an attractive option. The process of PGD is inconvenient and expensive, however, and is emotionally and physically draining.

For those who wish to avoid having a child with their family’s genetic disorder, weighing up the potential advantages and disadvantages of PGD against conventional prenatal diagnosis and the selective termination of an affected pregnancy entails weighing up the practical difficulties and costs of PGD against the fear of “needing” a pregnancy termination. Included in this equation may be the welfare of any children the couple already have and disruption to the wider social networks of both partners, including their employment. In discussing this with a couple, it may be helpful to encourage them to assess the strength of their objections to a pregnancy termination; this may clarify their thoughts and feelings.

Objections have been made to PGD because it is a technology that could be applied to choose between embryos on the basis of nondisease traits, including sex. If there are six healthy embryos and two are to be implanted, then it may seem very reasonable to allow the couple to choose the sex of the two embryos. There are good grounds for rejecting fetal sex selection in general, as discussed earlier, but are there any valid reasons for not permitting a couple in these circumstances to choose between the healthy embryos on the basis of sex or other nondisease traits for which testing might become possible, such as physical or even mental characteristics? If it were permitted for those using PGD because of an infertility problem to select between embryos on the basis of such traits, would the same be permitted for those who had no fertility problem but simply wished to select the characteristics of their child?

PGD can be seen as being located part of the way down the slippery slope to one type of “designer baby.” Although the burdensome nature of IVF technology and its costliness make it unlikely that many couples would wish to use it now, testing for nondisease traits may become available and the PGD technology is likely to improve, to be less burdensome. It is probably worth trying to arrive at a resolution of these problems before that occurs. There is no reason why a couple wishing to use such services would consult a clinical geneticist, so in that sense it is not a problem for “us,” but this area of “reprogenetics” lies so close to clinical genetics that we are bound to be affected by these developments.

One temporary resolution is to treat as distinct PGD for disease, for sex selection, and for selection on the basis of nondisease traits.

- PGD for disease presents fewer ethical problems than prenatal diagnosis and selective pregnancy termination and appears a reasonable option for those undergoing infertility treatment or with strong objections to pregnancy termination.
- PGD for sex selection is disrespectful to women and should not be performed except as a way of avoiding sex-linked disease (see the earlier discussion about prenatal diagnosis and sex selection).
- PGD for nondisease traits is not available at present because of technical limitations, and testing for socially important characteristics may not become available for many years, if ever. PGD on these grounds would not be part of the work of a clinical geneticist and should probably not be practiced at all. Such a development would be widely understood as a step toward a brave new world of genetically manipulated children.

The cloning of Dolly the sheep, announced in 1997, attracted acclaim and simultaneously also enormous concern. Human reproductive cloning has not yet been performed, but the world was compelled to acknowledge that it may be technically possible. In the context of clinical genetics, when might our patients seek reproductive cloning? What should our response be if/when such cloning becomes feasible?

Individuals who cannot have their own children because of infertility may find cloning an attractive option. Couples in which one partner has a dominant genetic disorder, or carries a sex-linked disorder or a chromosome rearrangement that could lead to problems with the child, may choose to clone the fertile, healthy, or noncarrier partner rather than run the risk of transmitting the condition to an affected child. It is difficult to envisage how the technology, or its public acceptance, will develop, but let us hope that biotechnology will be able to assist in such family scenarios before human cloning becomes available, so that the incentive to work for human reproductive cloning is lessened.

There would be very real concerns about the biological welfare of children born after cloning of an adult human because of cell aging effects, including telomere shortening and the accumulation of mitochondrial and other mutations. They may also suffer from infertility, and this could be a special problem for infertile males with Y-chromosome microdeletions. There would also be major concerns about the psychological welfare of the child clones of an adult “parent”; such a child would find itself uncannily similar to its mother or father when he or she was a child. The climate of expectations likely to surround these children in at least some families could well cause serious disturbances in their emotional development. If such children are born, however, it will be of the greatest importance to monitor their health and their emotional state, but without excessive intrusion into their family lives. Concerns about the privacy of families in which children were conceived by IVF prevented the systematic assessment of the long-term safety of such practices; such an opportunity must not be missed again, especially when the hazards appear to be much greater.

Finally, we turn to the analysis of ffDNA in maternal plasma as a means of performing prenatal genetic diagnosis without putting the pregnancy at risk by CVS or amniocentesis. This has been discussed earlier but here we consider the further development of its application in practice. This technique was initially used to detect paternally derived sequences that would not usually be present in the pregnant woman’s blood. This allowed fetal sexing (looking for Y chromosome sequences), identifying maternofetal Rhesus incompatibility or the transmission of a paternally derived autosomal dominant disorder. Recurrence of a recessive disorder can be excluded by showing that the father has transmitted his low-risk (nondisease) allele, or not excluded if his disease allele has been transmitted.

By comparing the quantitative yield of sequences from the different chromosomes, pregnancies carrying a fetus with a trisomy or other chromosome disorder can be identified; indeed *de novo* or inherited fetal CNVs can readily be detected.

The recent application of high-throughput genome sequencing technologies to this context is greatly extending the range of what can be discovered about the fetus (or embryo) from ~7 weeks’ gestation. By performing sufficiently “deep” sequencing, and especially if both parental genome sequences are available, it is possible to determine most of the fetal genome sequence, although this is still a research application and not readily available.

The immediate application of the new molecular sequencing technologies to reproduction then includes (i) carrier screening for autosomal recessive diseases and (ii) NIPD for Down syndrome and other chromosomal aneuploidies. For the first time, these two applications make realistic the prospect of drastically reducing, almost to nil, the incidence of autosomal recessive disease, Down

syndrome and other chromosomal anomalies. This raises profound questions about the type of society we want to live in, the extent to which we should regulate or control the biological composition of our communities, and whom we are prepared to welcome among us as fellow citizens. Would we want to change the nature of society so much? While one may feel a reluctance to take that road, the alternative may entail deliberately turning our backs on innovations that would prevent much suffering; is that not too high a price to pay for the nostalgic feeling of a now unattainably innocent virtue? There has been talk of “eugenics” for a long time; we now have the capacity to implement such policies, which used to be science fiction or mere “hot air.” We therefore need to be correspondingly more thoughtful about how we implement these developing technologies in practice.

## ACKNOWLEDGMENTS

I would like to thank many colleagues, collaborators, and students for helpful discussions over the years, most especially Professor Peter Harper. These discussions have corrected at least some of the faults in my thinking; those that remain are clearly my own.

### Biography

**Professor Angus Clarke** studied Medical and Natural Sciences at Cambridge, taking his BA Part II in Genetics, and qualified in Medicine from Oxford University. After registration, he worked in General Medicine and then in Paediatrics. He studied the clinical and molecular genetics of ectodermal dysplasia in Cardiff and then worked in clinical genetics and pediatric neurology in Newcastle upon Tyne, developing an interest in Rett syndrome and neuromuscular disorders. He returned to Cardiff in 1989 as Senior Lecturer in Clinical Genetics and is now Professor in Clinical Genetics. He has maintained his interests in Rett syndrome and ectodermal dysplasia and has developed further interests in genetic screening, the genetic counseling process and the social and ethical issues around human genetics. He represents the Chief Medical Officer for Wales on the UK Department of Health's Emerging Science and Bioethics Advisory Committee. He has (co)authored and edited seven books, including "Genetic Testing" (2011—jointly with Michael Arribas-Ayllon and Srikant Sarangi) and "Living with the Genome" (2006—with Flo Ticehurst). He established and directs the Cardiff MSc course in Genetic Counselling.

## Legal Issues in Genetic Medicine

*Philip R Reilly*

Venture Partner, Third Rock Ventures, Boston, MA, USA

### 31.1 INTRODUCTION

In this chapter, I address aspects of genetic medicine that raise important ethical and legal questions that have been or will be addressed by judicial decisions, legislation, or regulatory action by executive agencies. Years of debate, changes in relevant technologies, conflicting judicial opinions, inharmonious laws, and contrasting policy positions suggest how difficult it is to resolve key issues. For some topics, notably the laws concerning abortion, public policy seems to forever teeter on a shaky foundation. The main topics I shall consider are tort liability (malpractice issues) in clinical genetics, including the duty to warn; genetic counseling; abortion; genetic testing and adoption; newborn screening; regulatory oversight of new genetic diagnostic tests; regulation of direct to consumer genetic testing; genetic discrimination; surrogacy motherhood contracts; the regulation of human genetic research (especially informed consent); the regulation of human embryonic stem cell research; patenting genetic information and the Orphan Drug Act. The United States is far more litigious than most other nations, so some of the aforementioned topics are less relevant, for example, in Europe. Where possible, I will attempt to provide an international perspective.

No clear boundary demarcates legal issues in genetic medicine. Some topics, such as regulatory oversight of reproductive medicine and the impact of genetic testing on adoption, I will address only briefly. Other topics, such as the constitutionality of human cloning, the regulation of biobanks, reimbursement for the cost of medical foods, insurance coverage for genetic tests, and the use of DNA testing in immigration law, paternity disputes and forensics, I will not discuss.

The core theme to the legal issues that I address is that genetic data—information that can be ever more efficiently generated about each of us—holds significant potential for both good and harm, and for this reason, it is appropriate to craft societal rules that aim to maximize the former and minimize the latter.

A historical note is appropriate. One remarkable aspect of human genetics is how often advances (or, in some cases, apparent advances) in science have evoked a significant and sustained response from society expressed through the law. Perhaps the most infamous example was the widespread enactment during the first three decades of the twentieth century, both in the United States and internationally, of involuntary sterilization laws targeting the mentally retarded and the mentally ill. These laws reflected public reaction to naïve scientific conceptions that most such conditions had monogenic causes that were highly heritable and that therefore were in part preventable. In 1927, the United States Supreme Court upheld Virginia's involuntary sterilization law (1), and in 1934, the German government, significantly influenced by American eugenicists, enacted a similar Racial Hygiene Law. Involuntary sterilization programs flourished in more than a dozen countries, most notably the United States and Germany, until World War II; hundreds of thousands were sterilized (2). Although muted, programs of forced sterilization continue. For example, in 2010 a group of Uzbek women claimed that they were sterilized without their knowledge or consent as part of a government-backed population control program (3).

In the early 1970s, almost certainly in a well-intentioned effort to do good, legislators in 13 states enacted mandatory testing for sickle cell trait, often making proof of having been tested a condition of enrollment in the public schools. Such testing was not conducted as part of a comprehensive education and counseling program, and it outraged many in the African-American community. The resulting political hue and cry led to the enactment of a federal law that conditioned access to federal grants to states for sickle cell screening upon evidence that they were operating comprehensive voluntary programs (4).

Soon after it became apparent in the late 1980s that the ability to sequence the human genome was within

our grasp, concern about the possibility of abuse of personal genetic data became widespread. In the United States, the threat of genetic discrimination has been much discussed for the past 20 years, although somewhat less so since the enactment of the federal Genetic Information Nondiscrimination Act (5), which I discuss later. This sustained concern arose in no small part due to the patchwork nature of health care coverage in the United States. In virtually all other developed nations, citizens do not fear that a preexisting genetic condition could be grounds for denial or loss of coverage.

### 31.2 GENETIC MALPRACTICE AND THE DUTY TO WARN

From the perspective of tort law (the centuries-old, ever-evolving common law that defines what constitutes an actionable injury by one party to another), concerns about negligent behavior by health professionals who hold themselves out as able to practice genetic medicine fit relatively well within the broad rubric of medical malpractice. To establish negligence, the law requires that the injured party prove that he or she suffered an injury, that the harm occurred because of a breach of a recognized duty or standard of care, that the breach was the proximate cause of the injury, and that the damage should be actionable. There are other elements to this complex social equation—such as absence of contributory negligence—but for our purposes, the elements of a tort described above are sufficient.

The domain of malpractice law that is most relevant to genetic medicine is a diagnostic error, typically the failure to make a timely diagnosis. For example, each year, there are hundreds of lawsuits filed claiming that by failing to properly perform a breast examination, a physician delayed making the diagnosis of breast cancer, thus putting the plaintiff in a much more dangerous clinical situation than she would have been if the lump had been palpated at an earlier time. In genetic medicine, a comparable situation arises if a clinical geneticist, after completing his or her workup of a child, fails to make the correct diagnosis of a monogenic disorder and/or fails to properly counsel about recurrence risk. Diagnostic delay could in turn limit the benefits of proper treatment and exacerbate the ongoing injury caused by the genetic condition. In addition (and unlike most diagnostic challenges faced in pediatrics), however, a diagnostic error could indirectly result in the birth of a second affected child. For example, I know of several cases (most tort lawsuits are settled and very few are appealed, so it is difficult to collect good data) in which plaintiffs sued clinical geneticists alleging that negligence in failing to diagnose Fragile X syndrome was the proximate cause of the birth of a second affected child.

When they were first filed, now more than three decades ago, plaintiffs like these had to persuade the courts of the validity of either one of the two novel

causes of action: wrongful birth and wrongful life (6). Essentially, in wrongful birth lawsuits, the plaintiff must prove that had she known of a risk that should have been communicated to her, she would have avoided the birth of the affected child who, now in existence, is in need of special care. Over the years, supreme courts in more than one-half of the states have considered arguments favoring this novel cause of action. Although troubled by how to calculate appropriate damages, the courts have almost unanimously recognized this new tort. For example, in 2003, a Minnesota Court of Appeals held that physicians had a duty to warn a woman of the genetic diagnosis of her child and that if they failed to do so and she gave birth to a second affected child (with Fragile X syndrome) they could be liable (7). However, when such lawsuits included a cause of action by the child with the genetic disease, appellate courts have not recognized a right to sue. This is largely because the courts were unwilling to recognize a claim (often called “wrongful life”) premised on the argument that if a physician had properly performed his or her duty, the plaintiff would not ever have come into existence (8).

How does tort law articulate the duty that a clinical geneticist owes to the patient and his family? The clinician has the duty to use the knowledge available to him to attempt to diagnose the condition in a manner that other similarly trained professionals would conclude was reasonable. Such a vague standard may seem dissatisfying at first, but because it relies heavily on the (often unstated) rules of conduct within the specialty and because the plaintiff is unlikely to convince a jury of negligence if he cannot produce an expert in the field who will testify that a standard of care was breached, plaintiffs face significant hurdles in establishing a breach of conduct. In general, in medical malpractice law, most cases are dismissed in favor of the defendant or eventually settled within the coverage limits of the malpractice insurance policy. Of the relatively few cases that go to trial, the defense wins about 75–80%; this is probably also true when the issues involve genetic medicine. There are only a handful of appellate court decisions involving misdiagnosis of genetic disease. Of course, with the rapid growth of DNA-based testing, it is possible that litigation in this area will become more common.

Genetic medicine has generated significant debate about a core principle: confidentiality. For more than a century, tort law has held that physicians (and now all health professionals) must hold in confidence the information that they learn from and about their patients. There are of course certain exceptions to this—such as the recognized need to disclose facts to other physicians to assist in the proper care of the patient and the legislatively defined duty to report persons with contagious diseases. But, the discovery of a genetic fact about an individual—such as that his early-onset colon cancer was probably driven by a germline mutation—could be of immense clinical importance to his siblings, children,

and parents. This challenges us to reconsider the near-absolute nature of the duty of confidentiality. Should there be an exception for certain kinds of genetic information? If so, what should be the boundaries of that exception? Should the physician merely have a duty to warn his patient that he should communicate a genetic risk to his relatives? Should the physician have a right to reach out to first-degree relatives? What criteria determine when it is proper to do so? Should the physician ever be required to reach out to parties who are not his patients? If so, what constitutes appropriate discharge of that duty?

Discussion of a possible legal duty to warn third parties of risk despite an unavoidable breach of confidentiality derives mainly from a landmark California case, *Tarasoff v. Regents of the University of California* (9), in which the state's highest court held that a psychotherapist could have a duty to warn an individual if during the course of treatment a patient stated that he intended to kill that person and that there was a reasonable basis to conclude that the threat was real. The *Tarasoff* decision had a major impact on psychiatrists and other therapists, and various professional bodies spent years studying the feasibility of assessing risk to third parties and trying to outline the dimensions of a duty to warn. The boundaries of that duty remain uncertain.

An analogous problem arises in genetic counseling if the physician or counselor has discovered health information that is of potentially great importance to blood relatives of the patient. In clinical genetics, there is no clearly established legal obligation to warn persons who are not one's patients. This topic has been addressed repeatedly by blue-ribbon committees, by bioethicists and by legal scholars, but very few lawsuits have focused on them. In the United States, in the 1990s, two appellate courts considered the dimensions of the duty to warn nonpatient third parties about genetic risk. The Florida Supreme Court held that a physician who treated a woman with a dominantly inherited condition (medullary thyroid cancer) had a duty to warn her children about their risk for the disorder, but that the duty was discharged when the physician informed his patient of the risk to her children (10). In contrast, a New Jersey court held that a physician who treated a man for multiple polyposis had a duty to warn those known to be at risk for this (dominant) disorder of "avoidable harm," reversing a lower court decision that the physician had no duty to the children of his patient (11). Since courts in only a few states have ruled in this area, there is not yet a sufficiently large body of common law from which to discern a rule.

In general, professional bodies and academics have advocated that a health care professional should have a limited right to make a selective disclosure (a technical breach of confidentiality) to a few third parties when he or she has reason to believe that the index patient will not or cannot warn first-degree relatives. Practically speaking, the decision by the Florida Supreme Court that a physician discharges his duty to warn when he

informs his patient of risks to close relatives seems the best. It is unrealistic to impose a duty on physicians to reach out to people who are not their patients. For now, in the United States, the duty to warn appears satisfied by clearly informing one's patient of the possible risks to other family members. Perhaps the best way to resolve the issue of providing genetic risk information to third parties is to enact legislation. This has been done in a few countries, including Australia and Germany (12).

### 31.3 GENETIC COUNSELING

Although the practice of genetic counseling was introduced by a handful of physicians and research geneticists in the United States more than 60 years ago, it was not until the mid-1970s that it began to evolve into a health profession. With a few exceptions, persons who work as genetic counselors in the United States have earned an undergraduate degree and a master's degree from a genetic counseling program. Most practicing genetic counselors have also passed an examination that is developed and managed by the National Society of Genetic Counselors. It should be noted that certification is different from licensure, a term generally reserved for recognition by the state that an individual has demonstrated a specific level of professional training and skill. For well over a decade in the United States, genetic counselors, often supported by clinical geneticists, have lobbied the states to provide formal licensure of their profession. In the United States, state licensure is a key moment in the development of a profession. It is essential if genetic counselors wish to practice independently and be empowered to seek insurance reimbursement for their services. The movement for universal state licensure has proceeded slowly. At the time of this writing, eight states have enacted laws that confer licensure upon genetic counselors who meet the statutory requirements, and laws are being actively considered in six other states (13). It is likely that this trend will continue and that the majority of states will eventually adopt such laws; however, it may take another decade.

Genetic counseling is slowly evolving into a mature profession in Europe as well. Article 12 of the European Convention on Human Rights and Biomedicine requires that there be adequate genetic counseling before providing predictive or carrier testing. The Association of Genetic Nurses and Counselors, which represents counselors in the United Kingdom and Ireland, has convened a Working Group to develop a set of best practice recommendations (14). Genetic counseling is now selectively available in 38 European countries, but a survey of the practitioners in Europe found that the profession is still largely unregulated. In 13 of these nations, there were, as recently as 2006, not even any published professional guidelines. Many professionals working in Europe have called for more uniform training and favored more government regulation (15).

Lawsuits filed against genetic counselors proceed in the same manner and under the same legal rubric as those filed against physicians. It is uncommon, however, for a genetic counselor to be named as the main defendant in a malpractice lawsuit. This is because the vast majority of counselors work as the agents (under the legal oversight) of physicians. In most instances, the distinction is unimportant because the counselor and the physician work at the same institution and are covered by the same insurance plan.

Among the more common lawsuits in which genetic counselors are named as defendants are those that allege improper prenatal diagnosis, especially failure to offer an amniocentesis or failure to conduct certain tests (such as for carrier status in a couple at ethnic-based risk of one or more autosomal recessive diseases). Less common are lawsuits alleging failure to take a proper family history (that arguably would have uncovered a risk). A typical case, filed by parents of a child born with cri du chat syndrome against personnel employed at the University of Massachusetts/Memorial Medical Center in 2008, named two doctors, a nurse practitioner, and a genetic counselor as defendants. The key factual question was whether or not the team had properly informed the plaintiffs about the availability of amniocentesis. The case was settled out of court for \$7 million (16). One of the most important ways to reduce the risk of malpractice litigation over the subsequent birth of a child with a genetic disorder is to place a comprehensive note in the record that contemporaneously documents the actions taken and the information that was provided to the patient or the couple.

### 31.4 ABORTION

Although some states had enacted statutes that protected a woman's right to terminate her pregnancy before then, it was *Roe v. Wade* (17), a decision by the United States Supreme Court in January 1973 that recognized that the constitutionally protected right to privacy encompassed a woman's right to terminate her pregnancy under reasonable safety constraints until a fetus had developed to the point when it was viable (capable of life outside the womb). Since the *Roe* decision, the dimensions of the right to terminate a pregnancy have been repeatedly before the state legislatures and unendingly before the federal courts. Time and again it has appeared that the privacy right advanced by *Roe* would be lost, but (sometimes by the narrowest of votes) the US Supreme Court has never reversed the fundamental holding. Efforts by fervent opponents of abortion have succeeded in curtailing the reach of *Roe*—for example, securing laws that require parental consent for minors to obtain abortions, that limit state funding to pay for such procedures, and that require a woman to review “educational” material before she may proceed with a pregnancy termination. In addition, abortion opponents have successfully

blocked one method of late (and rarely used) abortion. A full review of abortion law is far beyond the scope of this chapter. I shall note a few of the more than 20 Supreme Court decisions that have addressed this bitterly contested issue.

Efforts to limit the impact of *Roe v. Wade* began immediately; during the 1970s, abortion opponents filed hundreds of such bills in state legislatures. Prophecies groups often filed lawsuits challenging the constitutionality of such laws on the day they were enacted. The next major case arrived before the US Supreme just 3 years later. In 1976, the high court struck down a Missouri law that required the consent of spouses and parents (of patients under age 18) before a woman could terminate her pregnancy (18). In 1979, the US Supreme Court (by an 8-1 vote) again invalidated state laws that required parental consent and held that the states must recognize a minor's right to demonstrate that she is mature enough to (in consultation with her physician) make a decision about termination independent of her parents (19).

Between 1977 and 1980, the US Supreme Court issued several opinions upholding the right of states to forbid the use of state Medicaid funds to pay for abortions for indigent women, decisions viewed as a victory for opponents of abortion (19–21), as they forced more poor women to continue unwanted pregnancies. In 1983, the Supreme Court struck down an Ohio law that required that second trimester abortions be performed in hospital (but upheld a provision that required parental or judicial consent to abortion for a minor) (22). In 1986, the high court struck down a law that required that a woman listen to a state-scripted speech designed to deter her from obtaining an abortion. In 1989, the Supreme Court upheld a Missouri law that forbid the use of public employees and facilities to perform abortions. In 1991, the high court upheld a federal regulation barring abortion counseling and referrals in family planning clinics that received any federal funds (23). In 1992, (by a 5-4 vote) the court upheld a Pennsylvania law that required patients to receive an “informed consent” booklet and imposed a 24-hour waiting period and a parental consent requirement. The only provision of that law that the court struck down was the spousal consent requirement. In 2000, the high court overturned a Nebraska law that banned the so-called partial birth abortions (24). However, in 2007 (in effect, reversing itself), the high court upheld a similar federal Partial Birth Abortion Ban of 2003, the first time the high court recognized the right of the government to forbid physicians from using a specific medical procedure. This closely decided case was the first in which the court had been realigned by the departure of Sandra Day O'Connor and the arrival of Samuel Alito. It has been nearly 5 years since the US Supreme Court issued an opinion involving the contours of *Roe*, and, at the time of this writing, no case is on its docket.

Over the past few years, there has been a sustained effort by abortion opponents in many states to enact

laws that interpret the protections provided to women by *Roe* as narrowly as possible. For example, as of April 2011, four states had adopted laws prohibiting abortions after 20 weeks of pregnancy (on the grounds that fetuses at that stage of development can feel pain) and similar bills had been introduced in more than 20 other states. Several states have enacted laws that forbid insurers from covering abortion services in their standard policies (women can still purchase coverage under more expensive supplemental policies). Activists in other states, such as Colorado and Montana, have sought to amend the state Constitution to define a person to include fertilized human eggs. For the foreseeable future, states will pass laws that challenge the limits of *Roe*; a few of them will make their way to the US Supreme Court. Based on the makeup of the court, it would not be surprising to see these restrictive state laws upheld. However, even though the US Supreme Court currently includes four justices whose view of constitutional law would favor letting each state decide the boundaries of abortion rights, I doubt the core holding in *Roe v. Wade* will be overturned.

### 31.5 ADOPTION

During the mid-1990s, some prospective adoptive parents began to inquire about the role of genetic testing in assessing the present and future health of an infant being placed for adoption (25). This caused concern that testing might be inappropriately used to choose among available children. In 2000, the American Society of Human Genetics (approving work of the Social Issues Committee) issued recommendations on this topic. Its three key points were that (1) all genetic testing of children in the adoption process should be consistent with testing that would be done on other children of similar age and condition, (2) that genetic testing should be limited to those conditions that manifest in childhood or for which preventive measures could be implemented in childhood, and (3) that in the adoption process, genetic testing should not be used to detect “predispositions to physical, mental, or behavioral traits within the normal range” (26).

A legal action for “wrongful adoption” was first recognized in the United States in Ohio in 1986. Since then this cause of action has evolved to include suits for fraudulently (knowingly) withholding important information material to the decision to adopt and negligently failing to learn or convey such information about the child. It is, for example, fraudulent to hide the fact that the birth mother abused alcohol throughout her pregnancy. Although there have been few cases turning on the disclosure of genetic data, in states where this issue can be raised, it is likely that courts will regard withholding clinical information that demonstrates or suggests that the child is burdened with a significant medical problem as material to the adoption decision. This could

also include medical facts about the birth parents. For example, it could be material that an infant was born to a woman with a late onset, serious, dominantly inherited condition.

In the past decade, lawsuits for “wrongful adoption” have become more common, especially with regard to international adoptions. In one prominent case in 2010, an American couple sued an agency in Russia when it discovered that the adopted child who they had been told had a good prognosis for normal development was actually the biological child of a woman who had abused alcohol during her pregnancy and who had fetal alcohol syndrome and an IQ of 53 (27). In about one-half of the states, it requires a court order to unseal an original birth certificate once an adoption is complete. But, beginning in 2000, a growing number of states (currently seven) enacted laws that permit adults who were adopted to have access routinely to their birth certificates. Similar bills have been introduced in New Jersey and New York (28).

The immense impact that DNA testing has had on paternity litigation—virtually ending what was once a common battle in the courts—is now only of historical interest. Because it can be used to rapidly and definitively establish parentage, in the United States, DNA testing, which is now universally recognized by the courts as a powerful evidentiary tool, helps women obtain child support for tens of thousands of children each year.

DNA testing to establish relationships is also used in the resolution of immigration disputes. In many nations (Denmark, Canada, Germany, and Switzerland, for example), DNA testing is used in programs that attempt to unite persons who seek entry as refugees and who claim they are the relatives of earlier immigrants (family reunification projects). The United States briefly operated a DNA testing program for similar purposes but suspended it in 2008 after finding that so many applicants were not related to their putative relatives. The United Kingdom also briefly used DNA testing in an attempt to establish the country of origin for African immigrants, but that project was suspended, in part due to criticism of the accuracy that the program claimed (29).

### 31.6 SURROGACY

Since the Supreme Court of New Jersey decided *In Re Baby M* case (30), legal issues involving surrogacy contracts have been frequently litigated. The famous New Jersey case arose after a physician whose wife had multiple sclerosis answered an advertisement offering surrogacy services. Mary Beth Whitehead agreed to become pregnant by artificial insemination with Dr. Stern’s sperm and to give up the child to him and his wife promptly after she gave birth. Upon delivery, the birth mother decided she wished to keep the child. When the ensuing custody battle reached the New Jersey Supreme Court, the justices, using an analysis based on the “best

interests of the child,” awarded custody to Dr. Stern but gave visitation rights to Mary Beth Whitehead. (When the child turned 18 years, she terminated her relationship with her birth mother).

In the past two decades, there has been a significant amount of litigation over the enforceability of surrogacy agreements, largely because few jurisdictions have enacted comprehensive legislation. In the United States, the law is in conflict; some state courts have refused to uphold agreements pursuant to the woman who agreed to become pregnant with the promise that she would give up the child at birth, whereas others have accorded a superior interest to the couple who engaged the woman by contract to act as a surrogate. California law routinely recognizes surrogacy agreements, whereas while in New York State, they are illegal. At least seven states are in accord with California. The legality of surrogacy agreements is emerging as an important issue for gay men who increasingly rely on them to have children. In this regard, Arkansas, which has one of the most permissive surrogacy laws, has attracted a substantial number of gay male couples.

In Europe, the practice of commercial surrogacy is in general tightly regulated, with some states forbidding payment of the gestational mother for the service she provides (31). In Ukraine, enabling legislation is quite liberal. Surrogacy contracts are recognized in India where the practice is widespread, raising ethical questions about the economic disparity between the parties to the agreement. Full discussion of this topic, the regulatory response to which remains in flux and about which there is a plethora of review articles in the legal literature, is beyond the scope of this chapter.

### 31.7 FROZEN EMBRYOS

Another subject of growing importance that has generated disparate holdings in different jurisdictions in the United States concerns the legal status and disposition of human embryos. Currently, there are more than 400,000 frozen human embryos in storage in the United States. Until a decade or so ago, many contractual agreements involving assisted reproductive technologies did not clearly delineate the process for the disposition of stored human embryos after the death of the biological parents or, more importantly, if they divorced. This was further complicated by the fact that neither the courts nor the legislatures had ever defined the legal status of stored human embryos. Over the past 20 years, a few court decisions have generated a majority view, but some legal issues remain unsettled. Neither has any appellate court accorded personhood to frozen embryos (a position that would be incompatible with *Roe v. Wade*) nor do the courts think of them as mere property. The leading case in this area, *Davis v. Davis* (30), decided by the Supreme Court of Tennessee, developed the idea that stored human embryos must be accorded “special respect,”

although it is unclear as to what that designation means and how it should shape disposition.

Embryo custody cases usually arise in the context of a divorce, and the key issue is to determine which of the biological parents shall have the right to control future use of the embryos. Generally speaking, in the absence of clear prior agreements to the contrary, the majority view is that the party wishing to avoid procreation should prevail, but some courts have noted that there might be circumstances in which this rule should not be followed (32). As access to the frozen embryos for reproductive purposes is generally more important to the woman, some have argued that she should have the primary legal interest. What then of the man, who no longer wishes to have a child with the woman? Has she the right to bear his biological child over his objection? Does a duty to support that child attach to him, even though the marriage ended before the pregnancy began? What are the implications of such child bearing for the laws of inheritance? Fortunately, most of these intractable problems will soon be viewed historically. Today, most legal agreements covering treatment of infertility anticipate the problems related to divorce and address such issues in a manner most courts would regard as definitive (33).

A vexing ethical problem concerns the proper disposition of frozen human embryos not destined to be brought to personhood by their genetic parents. In the United States, unlike a number of European countries, such as the United Kingdom and Italy (which limits the number of frozen embryos one can create), in vitro fertilization and embryo storage are largely unregulated. Most of the frozen embryos will never be used to attempt pregnancy. In a large survey conducted in 2008, more than half of the couples who did not want to attempt to have more general opposed donating their embryos to other infertile couples, and 43% did not want to destroy the embryos. About 66% were willing to donate them for research (which can be difficult to accomplish, as it often requires the direct engagement of the genetic parents with the research team). About one in five couples apparently prefer to hold the embryos indefinitely in storage (34).

The unresolved issues surrounding custody and/or disposal of frozen human embryos are just a few in a skein of difficult problems involving assisted human reproduction. Another important set of issues surrounds sperm donation, a process that has been widespread and largely unregulated in the United States for more than five decades. Most of the problems that have arisen pursuant to that practice will also complicate egg donation as it becomes more common. Among the more obvious concerns about sperm donation are inadequate health and genetic screening of the donor, limiting the number of donations, and guaranteeing the privacy of the donor. Perhaps the most notorious example of the failure of the regulatory process in sperm donation is a case in Michigan in which a donor contributed 11 samples, all of which were used and five of which resulted in babies

with the same serious genetic cause of neutropenia. Some nations (such as The Netherlands) limit the number of times a man can donate sperm, but most do not (35).

In recent years, coincident with the growth of the Internet, a large percentage of individuals who learn they were conceived with sperm donation are seeking to learn about, and often to meet, their genetic father. This has put great pressure on infertility clinics that are usually bound by a legal agreement not to disclose the identity of the donor. In Britain (and several other European countries), sperm donors must register and the offspring now have the right to learn the donor's identity on reaching the age of 18 years (35). I think the interest that children have in learning their biological heritage outweighs the privacy interest of the donor.

### 31.8 NEWBORN SCREENING

From its inception in the United States in 1962, newborn screening for genetic disorders has been implemented with state-based mandatory laws. In less than a decade, all 50 states enacted laws that required children to be tested for phenylketonuria. The laws were usually crafted in a manner that delegated power to the state department of public health to add tests to the screening program as it determined to be appropriate. Over the ensuing three decades, newborn screening in the United States became a set of regional programs; typically, a single state laboratory would serve a region (such as Massachusetts for most of New England), funded with state and federal funds and (in some cases) user fees. From the outset, some state laws provided exemptions to compulsory testing (typically, for claims based on religious beliefs), but little attention was paid to the consent process. The advent of tandem mass spectrometry in the late 1990s, a technology that significantly expanded the number of disorders that could be screened, led some jurisdictions to reconsider program operations. In Massachusetts, for example, when it was determined that screening for certain additional disorders should be considered experimental, a program was introduced to permit parents to “opt out” for certain tests. Still, the overall approach to newborn screening was that it was a valid exercise of the state's police power to require newborn screening on behalf of the public health. To my knowledge, the right of a government to operate compulsory newborn screening programs has been legally challenged only once. In 2001, a couple in Ireland challenged that nation's mandatory newborn test for phenylketonuria, arguing that the risk of the disease to their child was too remote to override their rights as parents to make an informed decision. The Supreme Court of Ireland found in their favor.

Recently, in the United States, there have been some important challenges to the operation of newborn screening programs. In 2006, the Texas Civil Rights Project, acting on behalf of five parents, sued the state to end the practice of the department of health of collecting and

indefinitely storing blood samples obtained for newborn genetic screening without having obtained informed consent. The plaintiffs prevailed, and the unconsented samples were destroyed (36). Texas subsequently enacted a new law that requires the provision of detailed information about newborn screening before taking a child's sample and that gives the parent the right to “opt out” of the testing. The law also provides that once they have become adults, individuals whose parents consented to the storage of a sample may, nevertheless, request that it be destroyed. In 2009, the Citizens' Council of Health Care and nine families sued the Minnesota Department of Public Health, alleging that it was collecting, storing, and using DNA samples from newborns without obtaining adequate consent, in violation of the state's 2006 genetic privacy law. At trial, the district court granted summary judgment in favor of the department of health, essentially ruling that the privacy law did not override the newborn screening law (which does include a parental opt-out provision). On appeal, the Minnesota Court of Appeals affirmed. Because only two state courts have considered challenges to newborn screening laws, it is not possible to discern a trend. It seems likely that “opt-out” provisions that avoid the expensive time-consuming process of obtaining pretest consent, but retain a mechanism through which parents can decline, will emerge as a compromise policy (37).

An emerging issue in newborn screening is to define under what circumstances, if any, screening samples may be used anonymously to conduct epidemiological research (38). Some experts have argued that these retained samples constitute an invaluable resource for improving human health; over 160 research questions have already been investigated by studying aliquots of samples (39). For example, the retained blood samples could be used over time to monitor levels of maternal exposure to teratogenic drugs or to certain widespread environmental pollutants. As of May 2010, 18 states had laws that addressed some aspects of this topic, but the laws vary widely in their approach (40). It would be beneficial to build a uniform approach to managing this issue, as is suggested in a recent helpful study done under the auspices of the Institute of Medicine.

State-based newborn screening has always been hobbled by inadequate funding. In 2008, the Congress enacted and the President signed the Newborn Screening Saves Lives Act of 2007, essentially an amendment to the Public Health Service Act to provide grants to the states to expand newborn screening, but funds to support the law were not appropriated. Until federal grant support is adequate, disparities among state and regional programs will continue. Although the states are becoming ever more similar in regard to the number of disorders for which they screen, the process is not likely to ever be completely uniform. For this reason, some children will be fortunate enough to be born in a state that screens for the disorder with which they are afflicted, whereas others will not be so fortunate.

### 31.9 PRENATAL AND CARRIER SCREENING

Prenatal screening is not conducted pursuant to state or federal law. Rather the standard practices—such as offering to test for fetal aneuploidies and to screen for neural tube defects—arise from policies advocated by recognized professional bodies such as the American College of Obstetricians and Gynecologists and the American Society of Human Genetics. Such promulgations have significant legal impact. They become a *de facto* standard of care that physicians ignore at their peril.

Similarly, with rare exceptions, carrier screening is not conducted pursuant to legislative fiat. Rather, from time to time—either because of promulgations by professional societies or as the result of malpractice litigation—there emerge new duties that must be incorporated into practice. Examples include the presumed duties to inform (1) an Ashkenazi Jewish couple of their risk for conceiving fetuses with Tay–Sachs or other recessive disorders that are comparatively prevalent in that ethnic group and (2) an African-American couple about their increased risk of bearing a child with sickle cell anemia. A duty arguably exists to take a genetic history of all couples, including questions related to consanguinity. For example, the discovery that a patient has a cousin with cystic fibrosis arguably triggers a legal duty to offer carrier testing.

The most famous of the few examples in which government bodies have aggressively pursued carrier screening involve screening for  $\beta$ -thalassemia. In Sardinia, a program initiated in 1978 has dramatically reduced the birth of children with this serious blood disorder in a single generation (41).

### 31.10 GENETIC DISCRIMINATION

Beginning in the mid-1980s, coincident with the growing awareness that we would gradually develop technologies to enable the collection of virtually unlimited amounts of genetic data from individuals, understandable concerns arose about the potential for misuse of this information. Early on (in public discourse, not by governmental regulation), genetic discrimination was defined broadly as the loss or denial of some desired goal (insurance, employment) because genetic information or family history suggested an increased risk of a disease, a reproductive risk, or a disability with that loss or denial creating an actual or potential economic harm. Note that the term did not include discrimination based on the presence of a disease state; for example, it did not include the refusal of a life insurer to offer a policy to a person with Huntington's disease.

Certainly, there are numerous lessons from recent history that support such fears, the most powerful being the ghoulish use of a pseudoscientific eugenics by the Nazis to justify the murder of countless Jews, gypsies, and mentally retarded and mentally ill persons. In the early 1970s, a number of states in the United States developed

compulsory programs to identify persons who carried an allele for sickle cell anemia. These short-lived programs (which failed to provide access to genetic counseling or adequate pretest education) did much to reenforce historical suspicions among African-Americans about the clinical and research communities.

The possibility that genetic data would be used by insurers, especially health insurers, to deny access to coverage was a major political topic throughout the 1990s. In the late 1990s, literally hundreds of bills were filed in virtually all the 50 states to address this fear. Many fewer, but still a substantial number of, states also regularly considered bills to address genetic discrimination in life insurance underwriting and in employment. By 2000, more than one-half of the states had enacted laws to prevent health insurers from labeling genetic risk as a preexisting condition and, thus, being able to deny or limit coverage should it manifest. Enactment of the federal Health Insurance Portability and Accountability Act in 1996, which included a provision that forbade the use of genetic information to deny coverage under the preexisting condition clause, complemented the state laws and probably helped to reshape underwriting behaviors.

A few states also enacted laws aimed at life insurance underwriting, but these for the most part only required that persons with various genetic risks be treated in the same manner and that the insurers be able to actuarially justify premium ratings. Early on, the American Council of Life Insurance took the position that genetic information was simply yet another form of medical information and that it had the right to review all such data as part of the process of deciding whether to issue a policy and at what rates.

Concern about genetic discrimination in the workplace was provoked in part by a long battle between women who worked in environments that could threaten a developing fetus. In the 1980s, several companies with manufacturing processes that exposed workers to high levels of lead made proof of infertility a condition of employment. These “fetal exclusion” policies were designed to protect the employers from lawsuits brought by women working in such settings whose babies evidenced the stigmata of lead poisoning. In 1985, women at Johnson Controls sued their employer alleging a violation of Title VII of the Civil Rights of 1964 as amended by the Pregnancy Discrimination Act of 1978. After 6 years, the US Supreme Court, reversing the lower courts, held that employers could not ban nonpregnant women from a workplace simply because they were exposed to agents that could cause birth defects (42).

By 1999, about 20 states had enacted laws to forbid employers from using genetic information in decisions about hiring or promotion. In 2000, President Clinton issued an Executive Order banning similar behaviors in the federal workplace. By 2004, about 32 states had laws to forbid or limit genetic discrimination in the workplace. There is little evidence to suggest that these state laws had

much impact. The federal Americans with Disabilities Act (1990), which forbids the use of most health information in determinations about hiring, had already accomplished most of what the state laws aimed to achieve. Furthermore, there were then relatively few genetic tests that could provide important information about one's capabilities of performing a particular job. With very rare exceptions, there have been virtually no complaints filed or no lawsuits initiated pursuant to these state laws.

One much discussed exception is an action taken in 2001 by the Equal Employment Opportunity Commission against the Burlington Northern Santa Fe Railway. The complaint alleged that the company was violating the Americans with Disabilities Act by forcing some employees (about 125 of a total of 40,000) who had filed disability claims for carpal tunnel syndrome to undergo a genetic test for hereditary neuropathy with liability to pressure palsies (HNPP). The case was settled in May 2002 through voluntary mediation; the company agreed to desist from testing and to pay damages to those that it had coercively tested. As part of the settlement, it was also permitted to state that it did not believe that it had violated the law (43).

After considering bills for more than a decade, the Congress passed and President Bush signed The Genetic Information and Nondiscrimination Act of 2008, popularly known as GINA (5). In essence, GINA prohibits group and individual health insurers from using a person's genetic information in determining eligibility and premiums; prohibits an insurer from requiring or requesting that a person undergo a genetic test; prohibits employers from using a person's genetic information in making employment decisions such as hiring, firing, or job assignments; and prohibits employers from requesting, requiring, or purchasing genetic information about individuals or their family members. GINA does not prevent health care providers from recommending genetic tests to their patients; does not mandate coverage for any particular test or treatment; does not prohibit medical underwriting based on current health status; does not address life, disability, or long-term care insurance; and does not apply to members of the military services. GINA should help to smooth the uneven nature of the protections offered by myriad state laws; at least 35 states now have employment laws and 47 have laws addressing aspects of health insurance (44).

As of May 2011, only one case, that of a Connecticut woman who claims she was fired after she disclosed that she underwent a double mastectomy because of a family history of breast cancer had been filed before the Equal Employment Opportunity Commission. Based on the history of litigation pursuant to similar state laws, some enacted more than a decade ago, I expect that litigation based on GINA will be small.

A new controversy over the use of genetic testing may be emerging in college sports. Effective August 1, 2010, the NCAA Division I legislation began to require that student-athletes provide as part of the medical

examination the results of a test for sickle cell trait. The individual may decline to be tested, but must sign a written release from liability should he be injured and turn out to be a carrier. The policy grows out of the settlement of a lawsuit against Rice University in 2006 after a student-athlete who turned out to have sickle cell trait died during a practice. Since 2000, the deaths of nine college athletes have been associated with sickle cell trait. In 2012, the American Society of Hematology sharply criticized the NCAA testing rules, calling them both overbroad and incomplete (45). It will not be surprising if over time such requirements expand to include testing for long QT syndrome, hypertrophic cardiomyopathy, and other genetically driven conditions.

### 31.11 REGULATION OF GENETIC DIAGNOSTIC TESTS

For nearly two decades, various groups, particularly genetic professionals and consumer advocacy groups, have expressed concern that under the existing regulatory framework in the United States, a laboratory may develop and commercially deploy a new genetic diagnostic test without first seeking some level of Food and Drug Administration (FDA) approval of that test. At the time of this writing, there is minimal oversight of genetic testing at the federal level and with a few notable exceptions (New York, California) in most states. There are signs that this situation may change. At the federal level, the FDA is evaluating whether or not to require prior approval of such tests. In 2008, the Secretary's Advisory Committee on Genetics, Health and Society (SACGHS) recommended that the DHHS create a mandatory public registry for genetic tests and genetic testing laboratories. This would constitute a welcome first step and would provide consumers with at least some data with which to decide about undergoing tests. In 2009, in the United Kingdom, the Science and Society Committee of the House of Lords issued a report on Genomic Medicine. It also advocated the creation of registry that would help consumers evaluate genetic tests. Probably because of the guaranteed health care coverage provided through the National Health Service, the Report specifically rejected the need for a genetic discrimination law such as GINA. It did, however, support the extension of the existing moratorium on the use of genetic testing in life insurance underwriting that has been in place in the United Kingdom since 1999 and is scheduled for review in 2011.

### 31.12 DIRECT TO CONSUMER GENETIC TESTING

In the United States, federal oversight of clinical laboratories is exercised through the Clinical Laboratories Improvement Amendments (CLIA) of 1988, the implementation of which falls within the jurisdiction of the FDA. Although FDA officials have asserted jurisdiction

over the regulation of genetic testing, they have not exercised it. Currently, many clinical genetic tests are offered pursuant to a provision of the law that permits a clinical laboratory that has developed a test to offer it from a single site. Under CLIA, certification and oversight are essentially delegated to state departments of public health. It is important to understand that, in general, this regulatory framework focuses on the operation of the laboratory and does not evaluate individual tests. The regulatory requirements that must be satisfied to gain CLIA certification are not particularly onerous. New York has exercised its right under CLIA to demand a higher standard for certification. In practice, many smaller states regard a laboratory that has been certified by New York as having met their standards. This is particularly true for genetic testing. Currently, New York requires prior review of every genetic test that a clinical laboratory proposes to offer. Furthermore, it has exercised jurisdiction over direct to consumer genetic testing laboratories, refusing to permit them to collect samples in the state unless they have met regulatory requirements. In 2010, the NIH, in an effort to improve public knowledge of genetic tests, launched a Genetic Testing Registry, a voluntary program that invites all laboratories to submit information about the tests that they offer.

In Europe, some states that are signatories to the Convention on Human Rights and Biomedicine have also signed the “The Additional Protocol on Genetic Testing.” Article 7 of the protocol requires that genetic testing for health purposes “may only be performed under individualized medical supervision.” Some European states have acted outside the Convention. For example, Germany has banned direct to consumer genetic testing.

Much has been written about the lack of regulatory oversight of direct to consumer genetic testing (30,46). A significant problem in developing adequate regulatory oversight is the unavailability of funds. Faced with this reality, what might be the key element of a simple yet effective oversight strategy? One thoughtful article identified the following five issues that must be addressed: (1) before testing adequate education must be provided and consent obtained, (2) laboratories must undergo an accreditation process and participate in quality assurance programs, (3) the scientific validity of the association between the disease state or liability and the genetic test result must be established, (4) laboratories must ensure that consumers have access to qualified professionals to help them understand the test results, and (5) claims about the value of the tests must satisfy consumer protection guidelines (47).

Direct to consumer genetic testing is a new service industry, operating in dramatic opposition to the decades-old model that required all test requests to be ordered by a physician. As the cost of testing continues to drop and the value of the tests continues to rise, it is likely that the direct to consumer testing will grow

substantially. Carrier testing for autosomal recessive disorders and pharmacogenetic testing are two areas that are poised for growth. Although the cost of testing for carrier status for perhaps 500 recessive conditions may soon be available for less than \$500, there is no evidence that most people will use the service.

### 31.13 REGULATION OF HUMAN GENETIC RESEARCH

In the United States, research involving human subjects is regulated by a body of rules embodied in the Federal Code of Regulations in 1978 (48). This relatively brief document provides the legal infrastructure for the Institutional Review Boards (IRBs) that dominate the local oversight of research involving human subjects, sets forth the elements of adequate informed consent, and provides special rules for vulnerable populations such as pregnant women, children, human embryos, and prisoners. From a regulatory perspective, oversight of human genetic research is covered by the same guidelines that cover other kinds of research involving human subjects. Although its opinions do not have the impact of regulatory authority, the NIH has for many years operated the Recombinant DNA Advisory Committee (the RAC), which provides an independent review of research proposals involving gene therapy. Its main concerns are the safety of the proposed study and the adequacy of the consent process.

The explosive growth during the 1990s of genetic research involving human subjects posed new challenges for IRBs, in part because the regulatory framework developed in the 1970s contemplated physical risks such as exposure to novel drugs, while genetic research posed informational risks such as wrongful disclosure of personal information. Novel questions emerged. What are the possible consequences of disseminating genetic data about individuals? Do relatives of subjects who are participating in clinical trials have a right to know about genetic discoveries that might be important to their health? Do researchers have a duty to make such disclosures? Do they have a right to do so? Who owns the DNA samples that are collected in the research setting? Should the consent process address ownership of a retained DNA sample? Does the donor of the sample retain any property rights in it? Should the team conducting the research disclose any economic ties that they have with a sponsoring company?

A decision by the Supreme Court of California in 1990 (49) remains the leading case on the topic of ownership of tissue. The court ruled that Moore did not retain an ownership on cells taken from his spleen that were used to start a cell line of value in leukemia research. It did, however, assert that the investigator has a duty to disclose to the prospective human subject any financial ties from which he may benefit should the research be successful.

Legal commentary (there have been very few lawsuits and even fewer appellate decisions to provide guidance)

concerning the regulation of human genetic research focus on risk of informational harm (such as discrimination in the workplace), disclosure of genetic data to others, adequacy of consent, ownership of tissue and the right, if any, to share in economic gains flowing from research, participation of children as research subjects, and use of human embryos.

One relatively new legal issue involving informed consent concerns the boundaries of the researcher's right to use samples obtained specifically for one study in other studies. Recently, the Havasupai Indians, who inhabit the deep crevices of the Grand Canyon, settled a lawsuit with Arizona State University growing out of a research project to study the genetics of the diabetes, which is common among the tribal members. One of the researchers involved also wished to use the samples to study the genetics of schizophrenia. In 2003, the tribe sued the university, alleging improper (beyond the scope of that delineated in the consent form) use of the samples. The parties disagreed over the clarity of the consent form on this point. In settlement, the university paid \$700,000 to be shared by 41 members of the tribe and returned all the samples to them (50).

### 31.14 REGULATION OF RESEARCH WITH STEM CELLS DERIVED FROM HUMAN EMBRYOS

Throughout the presidency of George W. Bush, it was federal policy to forbid the use of funds to support any research involving cells derived from human embryos (with the exception of 21 cell lines that were established prior to the implementation of the ban and which were suboptimal for research purposes). Although this certainly slowed progress in stem cell research, actions taken by a number of states, notably California, wherein 2004 voters approved a 10-year \$3 billion dollar effort to fund such work, may have more than compensated for the lack of federal funding. Shortly after becoming President, on March 9, 2009, Barack Obama lifted the executive order that had banned the use of funds for this purpose. Soon thereafter, two NIH scientists who oppose using human embryos in research sued to reinstate the ban, arguing that a federal law protecting embryos from research applied to the creation of cell lines. To the consternation of most scientists working in the field, a federal district court judge reinstated the ban. On appeal, the United States Court of Appeals of the District of Columbia overturned the lower court decision. As of the spring of 2011, the NIH has the right to fund research involving stem cells derived from human embryos.

### 31.15 GENES AND PATENTS

In brief, a patent is a governmental guarantee to market exclusivity for a defined period of time that is provided in response to a full disclosure of a discovery or

invention that satisfies certain tests. The right to seek protection of novel intellectual property is embodied in Article I, Section 8, of the United States Constitution. For more than two centuries, statutes, litigation, and evolving United States Patent and Trademark Office (USPTO) policy have shaped the definitions of what discoveries or inventions may be patentable. Similar bodies of law have developed in most, but not all, countries. The dimensions of patent policy in the United States and Europe are ever evolving. The first patent granted for a chemical composition in the United States was for adrenaline in 1906. The first patent involving a genetically engineered microorganism (a bacterium that degraded hydrocarbons) was issued in 1980 (51). In 1998, the USPTO issued a patent on the first transgenic animal, a mouse made susceptible to breast cancer. In the early 1990s, advances in genomic technology more or less marked the commencement of the rush to patent DNA sequences. As of 2010, about 40,000 patents have been issued in the United States that relate to about 2000 genes. Some single genes or proteins coded by them are the object of more than 100 patents. At one time, the NIH was a major filer of patents involving DNA sequences that suggested than unstudied genes (ESTs). Universities collectively own many patents covering aspects of human genes and often outlicense access to them (52).

United States policy encourages the creation of patents growing out of research conducted in part with federal funds. This position, the core principal of the Bayh–Dole Act (35 US Code Sections 200-212), is based on the premise that technology transfer to the private sector is most likely to benefit the general public. If the licensee does not develop that which has been licensed to it, the law permits the government to “march in” and offer licenses to others (a right that is rarely utilized).

The development of technologies to enable the detailed investigation of genomes and genes has posed several ongoing and challenging issues for national patent offices. This discussion will focus on US patent law, but it is important to note, especially in regard to genetics, that there are issues about which the policies of European nations and the United States diverge. A brief, but excellent, overview of possible solutions to current problems in regard to patenting DNA sequences in both the United States and Europe is available (53).

In general, academic laboratories do not engage in drug development beyond the preclinical stage; however, several medical schools operate genetic testing laboratories, those that sometimes constitute an important source of revenue. The controversy over gene patents is at the bottom a debate about whether newly discovered correlations between sequence variations and the presence of or risk for disease should be granted intellectual property protection. If such a patent is granted in the United States, the patentee has for a period of 20 years (from the date the patent was filed) exclusive control over the use

of that test, including the right to refuse licenses to other clinical laboratories to offer the test. During the past decade, several controversies have erupted over the right of a company or university laboratory to limit access to or charge high fees for access to a test. These have each been settled.

It is common for multiple patents to be issued concerning discoveries pertaining to a single genetic test. For example, at least 8 issued patents are relevant to testing for cystic fibrosis, at least 17 are issued in regard to testing for long QT syndrome, and 22 that pertain to testing for hereditary breast cancer. One concern has been that conflicting patents will create an intellectual property morass (often called a “patent thicket”) with one patent blocking another. Generally speaking, patent holders regularly solve these issues through cross-licensing or, sometimes, purchase of rights (54).

Over the past 15 years, there has been a tightening of the interpretation by the courts of key elements of patent policy as they apply to DNA sequences. For example, in 2009, a federal appellate court upheld the decision by the patent office to reject a patent application on the nucleotide sequence that governs activation proteins in natural killer cells on the grounds that it was an “obvious” topic to study (55).

Currently, the most watched lawsuit involving US patent policy in regard to genetics is a challenge brought by the American Civil Liberties Union (ACLU) and others against Myriad Genetics and the USPTO concerning its decision to issue patents that gave Myriad Genetics virtually exclusive commercial control over DNA diagnostic testing of the breast and ovarian cancer risk genes, *BRCA1* and *BRCA2*. Although the lawsuit attacked the issued patents on several grounds, the central argument was that a DNA sequence is an “unpatentable product of nature” (one of the exclusions from patentability recognized in patent law). A federal district (lower) court agreed with the plaintiffs, and Myriad appealed. The US Department of Justice intervened, filing a friend of the court brief that argued that it should be permissible to obtain patents on DNA sequences that have been altered for a beneficial purpose, but not on newly discovered sequence variations, such as those with mutations associated with a risk for breast cancer (essentially siding with the ACLU position). A federal appellate court reversed much of the district court’s decision in favor of Myriad (56), and the case was appealed to the United States Supreme Court. In 2012, the Supreme Court issued a decision in another case that in effect denied the patentability of a test based on a pharmacogenetic treatment algorithm (57). In so doing, it also returned the Myriad case to the appellate court for reconsideration in light of its new opinion.

Should the Myriad patent be invalidated, it will constitute a major revision in intellectual property policy, potentially threatening hundreds of other issued patents. Normally, a shift in policy of this magnitude is

implemented by federal legislation. Should it be implemented through litigation, it could have a chilling effect on commercial investment in genetic research. Regardless of whether Myriad Genetics prevails and the current rules on patenting DNA sequences for diagnostic purposes remain in place, there is sure to be much discussion about amending existing statutes to make such patents less restrictive. Recently, Belgium, France, and Switzerland enacted laws that can force foreign patent holders to grant use for public health needs. (53). In the United States, the SACGHS has recommended that there be a diagnostic use exemption for patents involving clinically relevant sequence variants. Of course, if such amendments to patent policy are enacted, industry may devote fewer resources to developing new tests.

Although bills proposing to amend patent laws are perennially before the United States Congress, there were few major changes to patent policy over the past half century. In 2012, the Congress passed and the President signed the Patent Reform Act of 2012. Its main impact is to adopt the “first to file” system, replacing the current “first to invent” system and bringing United States law in line with that of the rest of the industrialized nations. In addition, revisions to the concepts of novelty and nonobviousness may ultimately have some impact on patents involving DNA sequences. Part of the price of a patent is the disclosure of trade secrets. The new law includes provisions stating that failure to disclose the “best mode” cannot be used to invalidate or cancel a patent. This could be commercially beneficial to biotechnology companies by permitting them to maintain a competitive advantage even after a patent expires.

Although patent policy is determined by federal law, some states, perhaps concerned that GINA does not provide adequate protection against discrimination, are considering bills that would, if enacted, assert that genetic information is the property of the individual, “the unauthorized use of which interferes with both privacy rights and property interests of the individual.” This language is from a “Genetic Bill of Rights” introduced into the Massachusetts legislature in 2011 (58). If such laws are enacted, to the extent that they contradict federal intellectual property law, they will probably be overturned.

### 31.16 THE ORPHAN DRUG ACT

In 1983, the Congress passed and the President signed Public Law 97-414, popularly called the Orphan Drug Act (59). Few, if any, other laws have had such an important impact on patients with rare genetic disorders and their families. Essentially, the law offers a set of incentives to industry to pursue the development of drugs for comparatively small numbers of patients with uncommon disorders. It defines a “rare disease condition” as one that “affects less than 200,000 persons in the United States.” If a drug is approved by the FDA that has earned the designation as treating such a disorder, it is provided

with a substantial set of competitive advantages, the most important of which is blocking the approval of similar drugs for the same condition for 7 years. In Europe, analogous laws provide 10 years of market protection.

The ever-growing biotechnology industry makes extensive use of the Orphan Drug Act. For example, every drug approved in the United States in recent years for the lysosomal storage disorders, as well as many others, has been marketed with orphan drug status. In the 5-year period from 2007 through 2011, nearly one-third of all newly approved drugs were for orphan disorders. This protection is a positive incentive to the flow of capital into the biotechnology industry. Some, however, have argued that the law has anticompetitive effects and chills innovation (60).

### 31.17 CONCLUSION

For the most part, genetic information is being integrated into health care under a long-established medicolegal framework. Despite a growing stream of genetic data that is of potentially great importance to patients, few lawsuits have arisen from negligence in regard to the proper use or interpretation thereof. Concern over the duty to warn in genetic counseling has not emerged as a serious problem and is not likely to. The right to terminate a pregnancy before the point of fetal viability is under constant attack by those who oppose abortion. In the nearly 40 years since *Roe v. Wade* was decided, never has the membership of the United States Supreme Court been composed of a group that is in aggregate so unfriendly to *Roe*. Still, I think that the fundamental right provided by *Roe* will weather the storm. Genetic testing could with time become a regular feature of the adoption process, but it will not be used as a screening tool with which to select children. I think, instead it will be more akin to newborn screening—used to help the child. Virtually all aspects of assisted reproductive technology remain inadequately regulated in the United States (but better overseen and managed in Europe). Our society needs to craft relatively uniform social policies concerning the creation, storage, and disposition of frozen human embryos, sperm donation, and egg donation. Newborn genetic screening will continue to operate by consortia of state agencies, but with the rise of very low cost, high-throughput DNA sequencing, in time, a new legal model for newborn screening could emerge, including a private market. Prenatal screening, carrier testing, and direct to consumer genetic testing will continue to operate in a free market subject to the constraints imposed by the law of torts and contracts. Gradually, more regulatory structure will be imposed, eventually from a central authority such as the FDA. The long-standing and widespread fear of genetic discrimination has not materialized and, thanks to local and national laws that forbid it, it quite probably never will. The extant framework governing research with human subjects has demonstrated that it can properly

review and govern human genetic research (although it would be valuable to carefully reexamine the function of IRBs given that the rules that govern them have not been reconsidered in nearly 40 years). The vitriolic debate over the use of human embryos in research will fade away as the study of induced pluripotent cells becomes widespread. Existing patent rules can be effectively applied to intellectual property arising from DNA sequences. Recent litigation may be too disruptive of the system to be helpful. Legislative change is often more thoughtful and comprehensive. The Orphan Drug Act and related laws continue to constitute an important driver of large-scale commercial investment in genetic research.

### Biography

**Philip R Reilly, JD, MD**, is a Venture Partner at Third Rock Ventures in Boston, where he works to start companies to develop treatments for rare genetic disorders. From 2000 to 2006, he was the CEO and Chairman of the Board of Interleukin Genetics, Inc. Before joining Interleukin Genetics, Dr Reilly was the Executive Director of the Eunice Kennedy Shriver Center for Mental Retardation, Inc., a not-for-profit organization affiliated with the Massachusetts General Hospital. He has held numerous teaching positions, including Assistant Professor of Neurology at the Harvard Medical School and Adjunct Professor of Legal Studies at Brandeis University. Dr Reilly has served on many national committees chartered to explore public policy issues raised by advances in genetics. He is the author of six books and has published more than 100 articles in scholarly journals. Dr Reilly's most recent book, *The Strongest Boy in the World: How Genetic Information is Reshaping Our Lives*, was published by Cold Spring Harbor Laboratory Press in 2006. Dr Reilly has twice (2000 and 2003) been President of the American Society of Law, Medicine, and Ethics. From 1994 to 1997, he served on the Board of Directors of the American Society of Human Genetics. He is a founding fellow of the American College of Medical Genetics.

### 32.1 THE HYPOTHALAMIC–PITUITARY–GONADAL AXIS

Pubertal development and reproductive competence in mammals depend upon the coordinated efforts of the hypothalamic–pituitary–gonadal (HPG) axis. Gonadotropin releasing hormone (GnRH) neurons migrate from the nasal placode region into the hypothalamus along olfactory neurons. These neurons are dispersed throughout different regions of the brain although most affecting reproduction reside within the arcuate nucleus of the hypothalamus. In the arcuate nucleus, GnRH is synthesized and then secreted into the hypophyseal-portal vessels, where it then is delivered to the anterior pituitary gland (3). At the pituitary, GnRH binds to its G-protein-coupled transmembrane receptor in gonadotrope cells, which then synthesize and secrete the gonadotropins follicle stimulating hormone (FSH) and luteinizing hormone (LH). The gonadotropins stimulate the synthesis and secretion of sex steroids in the gonads (testosterone in males; estradiol and progesterone in females). Sex steroid negative feedback in both sexes results in inhibition at both the hypothalamus and the pituitary (3). Numerous growth factors including inhibins (A and B), activins, and insulin-like growth factors also play a role in normal HPG function. In addition, numerous neuropeptides, as well as altered function of the adrenal or thyroid glands, affect GnRH pulsatility that can impair function. It should also be recognized that gonadotropin-inhibitory releasing hormone (GnIH) has been identified, and initial findings suggest that this peptide inhibits gonadal function at each compartment of the HPG axis (4).

Aberrations of the HPG axis may manifest a wide range of clinical disorders in both males and females (Table 32-1). Somewhat arbitrarily, they have been

categorized into hypothalamic, pituitary, gonadal, and outflow tract abnormalities. First, a reasonable, systematic approach to the diagnosis of reproductive dysfunction in females is outlined (Figure 32-1). The genetic basis for disorders that comprise each diagnostic category will then be reviewed. Patients with reproductive dysfunction may be classified according to their gonadal status—as eugonadal or hypogonadal. Predictably, hypogonadism normally results in a more severe phenotype such as delayed puberty and infertility compared with patients who underwent normal pubertal development but subsequently manifest infertility.

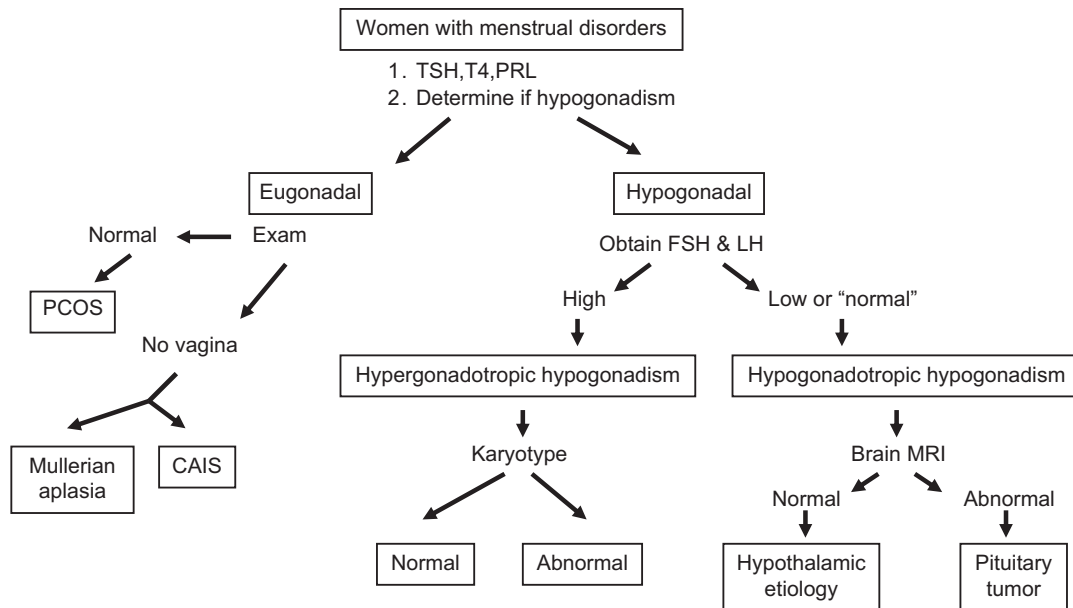

### 32.2 THE DIAGNOSIS OF HYPOGONADISM

The first step in identifying the underlying mechanism of reproductive dysfunction in females with menstrual dysfunction is to determine if hypogonadism is present (5).

**TABLE 32-1** Diagnostic Categories of Female Infertility

I. Hypogonadism
A. Hypogonadotropic hypogonadism
B. Hypergonadotropic hypogonadism
1. Abnormal chromosomes
a. Females: 45, X (with or without mosaicism); 46,XY
b. Males: 47,XXY; 46,XY
2. Normal chromosomes
II. Eugonadism
1. Ovulatory disorders—PCOS
2. Endometriosis
3. Disorders of the genital tract

**FIGURE 32-1** An overview of the diagnostic steps in females with reproductive dysfunction. The two most common causes of outflow obstruction causing primary amenorrhea are CAIS (complete androgen insensitivity syndrome) and Müllerian aplasia (Mayer–Rokitansky–Kuster–Hauser syndrome). PCOS=polycystic ovary syndrome; T4=thyroxin; TSH=thyroid stimulating hormone; PRL=prolactin. CDP=constitutional delay of puberty; IHH=idiopathic hypogonadotropic hypogonadism.

In females, serum estradiol levels are typically not accurate in the lower range, so it may be difficult to distinguish hypoestrogenism (<25 pg/mL) from normal early follicular phase levels (30–50 pg/mL). In the preovulatory period, the serum estradiol levels are usually about 200–300 pg/mL per mature follicle. If the patient completely lacks breast development, this is an important clinical indicator of hypoestrogenism (hypogonadism).

In females with breast development who have never menstruated (primary amenorrhea) and in young women with normal breast development who had menarche but have ceased menstruating (secondary amenorrhea), the determination of estrogen status is quite important (5). Both these clinical conditions indicate that estrogen was present at some time in the past, but this does not signify that estrogen status is now normal. Several different methods to assess estrogen status may be employed to determine estrogen status—the vaginal maturation index and a progestin challenge test. The presence of small parabasal cells (with a high nuclear/cytoplasmic ratio) obtained from a vaginal swab suggests hypoestrogenism, while the existence of superficial cells (large cytoplasm and small pyknotic nucleus) indicates normal estrogen status. Similarly, a reasonably normal 3–5-day menstrual withdrawal bleed following the administration of a progestogen indicates estrogen presence, while no bleed (or minimal spotting) suggests hypogonadism. Of course neither test is necessary if breast development is absent—this indicates a hypogonadal state. Importantly, the demonstration of hypoestrogenism does not define the specific etiology of the hypogonadism, it only indicates that hypogonadism is present (5).

**TABLE 32-2** Prevalence of Diagnostic Categories of Both Primary Amenorrhea (6) and Secondary Amenorrhea (7) in Females Are Shown

	Primary Amenorrhea (%) (6)	Secondary Amenorrhea (%) (7)
I. Hypogonadism		
A. Hypergonadotropic	43	11
1. Abnormal chromosomes	27	0.5
2. Normal chromosomes	16	10
B. Hypogonadotropic	31	42
1. Reversible	19	39
2. Irreversible	12	3
II. Eugonadism	26	46
1. Ovulation disorder	8	39
2. Genital tract obstruction	18	7

If the insult resulting in hypogonadism occurs before or during puberty, pubertal development may be absent or arrested. Delayed puberty in females is usually defined as either the absence of breast development (thelarche) by age 13 or the absence of menses (menarche) by age 15, both of which are 2.5 standard deviations above the mean for North American adolescents. However, hypogonadism may instead ensue after pubertal development has been completed. The most common diagnoses of hypogonadism are shown in Table 32-2. For patients with evidence of estrogen production, most patients with menstrual dysfunction will have anovulation—usually

caused by polycystic ovary syndrome (PCOS) (in 70%), but also by thyroid dysfunction or hyperprolactinemia. A small percentage of patients will present with uterine or vaginal outflow obstructive disorders, which will be determined by pelvic exam.

### 32.3 CATEGORIES OF HYPOGONADISM

Once the diagnosis of hypogonadism is established, the precise etiology should be determined. The hypoestrogenic state results in removal of gonadal steroid negative feedback, so the performance of serum FSH and LH levels will discern if the defect is gonadal or hypothalamic/pituitary in origin (Figure 32-2) (5). Elevated serum gonadotropins on at least two occasions several weeks apart indicate a diagnosis of *hypergonadotropic hypogonadism* (or gonadal failure). A karyotype should be performed in females with hypergonadotropic hypogonadism who fail to undergo normal puberty to rule out a chromosomal abnormality—most commonly, a 45,X cell line with or without mosaicism or a pure 46,XY cell line (6). As might be expected, these karyotypic abnormalities in hypergonadotropic hypogonadism are much more common in patients with primary amenorrhea rather than secondary amenorrhea (Table 32-2) (6,7).

When serum gonadotropins are inappropriately low (or normal) in the hypogonadal female, hypothalamic/pituitary dysfunction is present indicating *hypogonadotropic hypogonadism*. Once extreme stress, eating disorders, or excessive exercise are excluded and there is no central nervous system (CNS) tumor by MRI, the most common cause is normosmic idiopathic hypogonadotropic hypogonadism (nIHH) or Kallmann syndrome (KS) if idiopathic hypogonadotropic hypogonadism (IHH) is accompanied by anosmia (or hyposmia). Although the prevalence of karyotype abnormalities is much less frequent than those with hypergonadotropic hypogonadism, approximately 2–3% of patients with hypogonadotropic hypogonadism could have chromosomal rearrangements (8). In fact, one of these balanced translocations resulted in the discovery of a new gene (*WDR11*) involved in hypogonadotropic hypogonadism (9). In patients with extreme short stature and hypogonadotropic hypogonadism, other conditions such as growth hormone (GH) deficiency, hypothyroidism, or combined pituitary hormone deficiency (CPHD) could be present (3).

### 32.4 EUGONADAL INFERTILITY

If the patient with menstrual irregularity has evidence of adequate endogenous estrogen production, then anovulation, usually from PCOS, will be present in most patients if thyroid disease and hyperprolactinemia have been excluded. Less commonly in routine infertility patients, obstruction of the genital tract (uterus, vagina or both)

**FIGURE 32-2** The hypothalamus–pituitary–gonadal axis is shown. (A) Hypogonadotropic hypogonadism is depicted. Low estradiol fails to trigger a rise in GnRH and FSH indicating that the defect is at the hypothalamus or pituitary (the hypothalamus and pituitary are shaded lighter to reflect hypofunction). (B) Hypergonadotropic hypogonadism is shown. Low estradiol elicits an appropriate rise in hypothalamic GnRH and pituitary gonadotropins indicating the defect is the lack of a gonadal response (the ovary is shaded lighter to represent hypofunction).

could be present. However, in women with primary amenorrhea, the two most common eugonadal disorders include congenital absence of the uterus and vagina (CAUV) and complete androgen insensitivity syndrome (CAIS) (6). These disorders would be ascertained by the finding of an absent vagina on pelvic exam.

### 32.5 SPECIFIC DISORDERS IN EACH DIAGNOSTIC CATEGORY

The molecular basis for female infertility will now be detailed according to the diagnostic categories discussed above. Rarer but more serious hypogonadal causes of infertility will be considered—first hypogonadotropic hypogonadism and then hypergonadotropic hypogonadism. This will be followed by the more commonly encountered disorders in eugonadal individuals; unfortunately, the pathophysiologic basis for eugonadal causes of infertility (other than secondary to infection) is not as well understood as for the hypogonadal category.

### 32.6 HYPOGONADOTROPIC HYPOGONADISM

Patients with IHH who do not exhibit CNS tumors by MRI of the brain (with and without gadolinium) have a high likelihood of having a genetic form of hypogonadism. Hypoplasia or absent olfactory tracts and bulb suggests the diagnosis of KS, which pairs IHH with olfactory dysfunction (anosmia or hyposmia) (3). Other congenital anomalies may accompany IHH/KS, which could provide a clue to the etiologic gene. These include: unilateral renal agenesis, midline facial defects, dental aplasia, neurologic deficits such as synkinesia, hearing loss, or visual abnormalities as these may be associated with IHH/KS (3).

### 32.6.1 Genetic Causes of Hypogonadotropic Hypogonadism

Hypothalamic causes are discussed first (Table 32-3), followed by pituitary etiologies.

**32.6.1.1 KAL1.** Men and women with KS demonstrate IHH and anosmia, further supporting the common developmental pathway of GnRH and olfactory neurons, which migrate from the olfactory placode region into the brain. *KAL1* mutations on chromosome Xp22.3 have been described in males with X-linked recessive KS (10,11). *KAL1* encodes anosmin-1, a putative neural cell adhesion molecule is involved in the migration of GnRH and olfactory neurons during embryologic development. *KAL1* mutations account for ~33–70% of familial cases of KS and 3.1–27.8% of apparently sporadic forms of IHH with anosmia (12,13). There is currently no convincing evidence that *KAL1* mutations are pathogenic in females.

**32.6.1.2 FGFR1 and FGF8.** Mutations in the gene encoding the fibroblast growth factor receptor-1 (*FGFR1*) cause a form of KS designated *KAL2*. This gene was identified by positional cloning aided by the availability of several patients with contiguous gene deletion syndromes on chromosome 8p11.2–p12 who also had KS (14). No *FGFR1* gene deletions were identified in 43 additional KS patients, but 12/129 (9%) had heterozygous *FGFR1* point mutations (14). Subsequent studies of both males and females with autosomal dominant IHH/KS indicated that *FGFR1* mutations may cause either anosmic/hyposmic KS or nIHH (14–18), as well as in patients with subsequent reversal of their hypogonadism (19). Current evidence indicates that *FGFR1* mutations

occur in up to 10% of either KS or nIHH (17). Some patients with *FGFR1* mutations may also have associated neurologic abnormalities and midfacial defects similar to those with X-linked KS. As is true in many autosomal dominant diseases, a complicating and challenging feature among families with inactivating *FGFR1* mutations is variable expressivity. A number of mutations leading to nIHH or KS have been described, many of which impair fibroblast growth factor (FGF) signaling in vitro (14,16,17,20,21).

The human *FGFR1* gene is composed of 18 exons contained within 56 kb of genomic DNA encoding a single transmembrane receptor. The receptor consists of three immunoglobulin (Ig)-like domains, a heparin-binding domain, and two tyrosine kinase domains. *FGFR1* binds ligands FGF1 and FGF2 with high affinity, involving a K18K sequence essential for receptor activity and interaction with heparin (22). As both *FGFR1* and anosmin-1 utilize heparin sulfate proteoglycans, anosmin-1 could be a ligand for *FGFR1*. The importance of the FGF pathway in GnRH neuron development has been demonstrated by a number of studies. *FGFR1*–3 are expressed in the nasal placode about E10.5 in the mouse when GnRH neurons first appear. *FGFR1* and *FGFR3* are also expressed in GnRH neurons at E15.5 and postnatally in the mouse (23). In addition, an *FGFR1*-dominant negative mutant results in an attenuation of neurite outgrowth following stable transfection. These experimental findings indicate that FGF signaling is involved in GnRH neuron specification, migration, and axonal targeting (23).

Both activating and inactivating *FGFR1* mutations have been described. In fact, the first *FGFR1* mutations described were activating ones that cause craniosynostosis and skeletal anomalies such as craniofacial-skeletal dysplasia (Jackson–Weiss syndrome), Pfeiffer syndrome, trigonocephaly, osteoglophonic dysplasia, and Antley–Bixler syndrome (24–27). However, it is the inactivating *FGFR1* mutations that cause IHH/KS although skeletal effects may occur in both types of mutations.

Fortuitously, mutation in *FGFR1* was known to occur in a region where ligand FGF8 binds. Therefore, *FGF8* became a plausible physiologic candidate gene, and heterozygous mutations have been identified in about 1% of nIHH/KS patients (28). These findings suggested that *FGF8* mutations lead to autosomal dominant inheritance although one additional patient had biallelic mutations. Nevertheless, the finding that both *FGF8* and *FGFR1* genes possess mutations in nIHH/KS patients indicates the importance of FGF signaling in GnRH neuronal development and function.

**32.6.1.3 KISS1R.** Even though kisspeptins, which are ligands for G-protein-coupled receptor 54 (GPR54), were originally isolated from melanomas (the first kisspeptin was denoted as metastin), the significance of this pathway in reproduction did not become appreciated until the positional cloning of the *GPR54* (now known as *KISS1R*) gene in nIHH patients. Independently, two

groups studied consanguineous families by linkage analysis and demonstrated highly significant LOD scores for chromosome 19p13, where *KISS1R* resides (29,30). In a Saudi Arabian family, DNA sequencing revealed a homozygous missense mutation, while another unrelated patient had compound heterozygosity for a nonsense mutation (R331X) and a read through mutation (X399R) (30). All three mutations demonstrated impaired signal transduction (reduced inositol phosphate production) in vitro (30). A French group identified a homozygous missense mutation and a homozygous 155 bp deletion in two different nIHH patients (29). The missense mutation was later found to also impair GPR54 signaling (31). No definitive mutations in the *KISS1* ligand have yet been identified in humans but they are likely to exist.

*KISS1R* mutations that were studied in vitro demonstrated reduced GnRH secretion, but had some impaired gonadotropin response to pulsatile GnRH (29,30). Affected females successfully responded to gonadotropin ovulation induction with achievement of normal pregnancy, delivery, postpartum recovery and lactation (32). As expected in an autosomal recessive disease, heterozygous offspring were normal (32). Further support for the role of GPR54 in normal puberty comes from the *KISS1R* knockout (KO) mouse, which was hypogonadal. Homozygous KO mice demonstrated a normal anatomic location of GnRH neurons and normal GnRH content in the brain, suggesting that *GPR54* signaling is important in GnRH release (30). Several additional rare sequence variants of *KISS1R* have been described, some of which are likely to be functional, but their consequences are not completely understood (33).

Kisspeptins are most highly expressed in the placenta, but they are also found in the anteroventralperiventricular (AVPV) nucleus and the arcuate nucleus of the hypothalamus. Neurons from these nuclei send projections to the medial preoptic area of the hypothalamus, where GnRH neurons reside and secrete GnRH into the hypophyseal-portal system. It is known that GPR54 is present in 50–75% of GnRH neurons (34–36). The transition from the prepubertal state to puberty is marked by kisspeptin activation of GPR54 (37). Kisspeptin infusions result in increased pituitary gonadotropin secretion, an effect that can be abolished by GnRH antagonist administration, indicating a hypothalamic effect of kisspeptin upon GnRH release (37). Gonadectomy increases and sex steroid replacement decreases kisspeptin expression in the arcuate nucleus, whereas the opposite is true in the AVPV nucleus (38). These findings suggest that kisspeptin signaling may be important in steroid feedback and the LH surge. Mutations in *KISS1R* nicely exemplify how the identification of even rare mutations in a gene (<1% of nIHH patients) can lead to profound improvement in our understanding of human physiologic processes.

**32.6.1.4 *LEP* and *LEPR*.** Leptin is a protein secreted by white adipose tissue that participates in body weight regulation by decreasing food intake and increasing energy

expenditure. Leptin is also involved in the modulation of neuroendocrine, reproductive, immune, and cardiovascular systems, particularly in energy deficient states. Its role in regulating the HPG axis in humans is supported by a study in which leptin administration resulted in ovulation in three of eight women with hypothalamic amenorrhea (39). Leptin binds to the leptin receptor (LEPR), a member of the cytokine family of receptors. Leptin signaling involves activation of the STAT3 pathway intracellularly as well as interaction with the melanocortin 4 receptor (MC4R) to produce anorectic effects (40).

Further support for leptin's role in reproduction has come from the identification of human mutations in individuals with severe, early-onset obesity. Mutations in leptin (*LEP*) (41–44) or *LEPR* (45,46) lead to hyperphagia and morbid obesity in early childhood. The first human *LEP* gene mutation was characterized in a family with two obese prepubertal children who had extremely low serum leptin levels, but all subjects were prepubertal (42). Subsequently, a second *LEP* mutation was identified in a consanguineous family containing three affected obese individuals (41). A 14-year-old female presented with primary amenorrhea and a 22-year-old male had irreversible pubertal delay, low testosterone, low gonadotropins, but a normal response to exogenous hCG and GnRH. Both affected family members demonstrated homozygosity for a missense *LEP* gene mutation impairing leptin secretion in vitro (41). The phenotype of humans with *LEP* mutations is similar to leptin-deficient *ob/ob* mice as they manifest extreme obesity, hyperinsulinemia, and hypogonadotropic hypogonadism, but unlike the mice, affected humans do not have hyperglycemia, hypercortisolemia, or stunted height (41). At least 12 *LEP* mutations have been identified to date in individuals with extreme, early-onset obesity, indicating that the prevalence in all IHH/KS patients is very low (47). The possibility of *LEP* mutations should be considered in nIHH patients with extreme obesity and low serum levels of leptin.

Leptin-resistant *db/db* mice have mutations of the *Lepr* gene, but until recently (47), only one human *LEPR* mutation was described (46). Leptin resistance was observed in a family of severely obese females with nIHH and elevated serum leptin levels. Homozygosity for an *LEPR* splice mutant resulted in exon skipping, thereby truncating the receptor so that it lacked both the transmembrane and intracellular domains (46). In addition to IHH, this patient also had mildly reduced secretion of GH and thyroid stimulating hormone (TSH) (46). Subsequently, a subset ( $n=300$ ) of a large cohort of 2100 early-onset obese subjects who were negative for mutations in known obesity genes was screened for *LEPR* mutations (47). Nearly 3% of subjects had *LEPR* mutations (missense or nonsense), all of which impaired *LEPR* signaling in vitro. Affected individuals also demonstrated hyperphagia, altered immune function, and delayed puberty secondary to nIHH. Of interest, serum leptin levels were not different from similarly obese patients

without *LEPR* mutations, and somewhat surprisingly, the clinical features of patients with *LEPR* mutations were less severe than those with *LEP* mutations (47).

**32.6.1.5 *NR0B1*.** Mutations in *NR0B1* result in an X-linked recessive form of IHH coupled with adrenal hypoplasia congenita (AHC) (48). This gene was cloned from the dosage sensitive sex (DSS) reversal region of chromosome Xp21 in humans, which when duplicated was reported to cause undermasculinization in 46,XY males (48,49). The identification of *NR0B1* was aided by the findings from patients with a contiguous gene deletion sequence on Xp21 manifesting Duchenne muscular dystrophy, glycerol kinase deficiency, as well as AHC/IHH. The human *NR0B1* gene encodes for the DAX1 (DSS-AHC critical region of the X chromosome, gene 1) protein, which is a member of the steroid hormone receptor superfamily that has no known ligand (and therefore is an orphan receptor). DAX1 is a transcription factor necessary for normal development of the hypothalamus, pituitary gonadotropes, and adrenal cortex (48,49).

Males with *NR0B1* mutations usually present with adrenal failure in infancy or childhood due to an underdeveloped permanent zone of the adrenal gland (48,49). Affected children who are adequately treated with adrenal steroids manifest delayed puberty due to IHH. Occasionally, patients develop adrenal insufficiency later in life or only after targeted testing of the adrenal gland (50–52). Unfortunately, patients with *NR0B1* mutations do not respond well to gonadotropins and may show minimal response to pulsatile GnRH, implicating an inherent defect in the gonads (53,54). A large variety of different *NR0B1* mutations, including deletions and point mutations, have been reported in AHC patients, which have been almost completely confined to males (55). However, a homozygous *NR0B1* mutation was reported in an IHH female who did not have adrenal failure but had two males with AHC in her family. Her homozygosity was thought to be due to a gene conversion event. Female carriers with *NR0B1* mutations rarely may manifest delayed puberty (56).

DAX1 regulates gonadotropin secretion at both hypothalamic and pituitary levels (55,57). It may also inhibit transcription of another important steroid receptor, Steroidogenic factor-1 (SF1), which is expressed in the same tissues and is important in sexual differentiation (55). Although initial data suggested that *NR0B1* might be an ovarian determinant gene because of its localization within the DSS region on Xp, a conditional KO of the mouse ortholog of *NR0B1* (*Nr0b1*) did not confirm this hypothesis (58). Instead, these mice demonstrated normal ovarian development and function; however, male mice displayed degeneration of testicular germinal epithelium independent of gonadotropin and testosterone abnormalities (58). These findings suggested that *Nr0b1* may be more important in spermatogenesis than in ovarian development.

**32.6.1.6 *PCSK1*.** We are only aware of only one case of IHH caused by a mutation in the prohormone convertase, subtilisin/kexin type 1 (*PCSK1*) gene (59–61). The affected female patient presented with extreme early-onset obesity, IHH, hypocortisolism, and abnormal glucose homeostasis. She had elevated plasma proinsulin and pro-opiomelanocortin (POMC) concentrations, and extremely low insulin levels (59–61). Compound heterozygous *PCSK1* mutations were detrimental: a frameshift mutation predicted protein truncation, while the missense mutation prevented processing and lead to its retention in the endoplasmic reticulum (59–61). Because of the similarity of this proband to that of the *fat/fat* mouse, it appears that molecular defects in prohormone conversion could constitute a mechanism for obesity and endocrine disease common to humans and rodents.

**32.6.1.7 *PROKR2* and *PROK2* (KAL3 & 4).** The genes for prokineticin-2 (*PROK2*) and its receptor (*PROKR2*) were first suggested as candidate genes for IHH/KS because the *Prokr2* KO mice, lacking a 7-transmembrane GPR, demonstrated impaired olfactory development and decreased numbers of GnRH neurons (62). Similarly, KO of the gene for the ligand, *Prok2*, impaired normal olfactory bulb development (63). When 192 KS patients underwent DNA sequencing for both genes, 10 mutations in *PROKR2* (5.2%) and 4 (2.1%) mutations in *PROK2* were identified (64). However, the mode of inheritance was unclear as *PROKR2* mutations were either heterozygous, homozygous, or compound heterozygous while the *PROK2* were heterozygous. Since these studies, it now appears that mutations in both genes are likely to be autosomal recessive as segregation analyses in informative families, in which heterozygous parents are unaffected, and only the homozygous offspring are affected (65). Therefore, it is possible that the reported prevalence of these mutations is somewhat overestimated as heterozygous carriers are included. However, the finding of either heterozygous *PROK2* or *PROKR2* mutations in IHH/KS patients could indicate that they possess a mutation in the second gene (which has been reported—see below).

**32.6.1.8 *CHD7* (KAL5).** Mutations in the human chromodomain helicase DNA-binding protein 7 (*CHD7*) gene cause CHARGE syndrome, an autosomal dominant or sporadic disorder consisting of Coloboma of the eye, Hear defects, choanal Atresia, Retardation of growth and development, Genitourinary anomalies, and Ear abnormalities (vestibular and auditory) (66). The gene was initially identified by studying two CHARGE patients with microdeletions on chromosome 8q12. The nine genes within this region were sequenced in 17 CHARGE syndrome patients without deletions, and 10 heterozygous *CHD7* mutations (7 nonsense, 2 missense, and 1 potential splice mutant) were identified (66). *CHD7* mutations occur in 60–80% of patients with CHARGE syndrome and span across the entire gene, but there is currently no correlation between genotype and phenotype and most

are de novo (66,67). *CHD7* appears to play an important role in the nucleus in binding to chromatin and regulating gene expression (68,69).

Mutations of *Chd7* generated by ENU mutagenesis techniques in mice corroborated human CHARGE syndrome. Phenotypic effects observed in these heterozygous mice included cleft palate, choanal atresia, cardiac septal defects, hemorrhage, prenatal death, vulvar and clitoral defects, and keratoconjunctivitis sicca (70). *Chd7* is ubiquitously expressed by semiquantitative RT-PCR in fetal and adult tissue, including the olfactory epithelium, eye, inner ear, and vascular system (66). At E10.5 in the mouse, *Chd7* is selectively expressed in the forebrain, olfactory pit, optic vesicle, hindbrain, cardiac outflow tract, facio-acoustic preganglion, and mandibular portion of the first branchial arch (71). Additionally, loss of function in gene-trapped reporter mice resulted in embryonic lethality at E10.5 (72), which suggests that homozygous mutations might also be lethal. *Chd7* expression in this relevant animal model was observed in the brain, retina, ear, craniofacial structures, pituitary, heart, and kidney at the expected time of endogenous *Chd7* mRNA expression (E10.5) (72).

Several studies implicated the *CHD7* gene in IHH/KS (73). The phenotypic findings of CHARGE syndrome and KS overlap as some CHARGE patients have anosmia and hypogonadotropic hypogonadism. However, many of the CHARGE patients were not yet pubertal, so the absolute diagnosis of IHH was not able to be satisfied. It was hypothesized that KS might represent a mild allelic variant of CHARGE syndrome, which was supported by the identification of sporadic heterozygous *CHD7* mutations in ~6% of nIHH and 6% in KS patients who did not fulfill criteria for CHARGE syndrome (73). Developmental expression within the hypothalamus and within the GnRH neuronal migratory pathway along with the presence of human mutations indicates that *CHD7* has an important role in puberty and reproduction (73).

**32.6.1.9 NELF.** The gene for nasal embryonic LHRH factor (*Nelf*) was cloned and characterized from migrating GnRH neurons using differential screening techniques in mouse (74). High levels of mRNA and protein expression were identified in the forebrain, olfactory epithelium, and olfactory pit of embryos with maximal expression between E12.5 and E14.5 in the olfactory epithelium and olfactory pit (74). These authors suggested that NELF may serve as a common guidance cue for olfactory axon projections and subsequent migration of GnRH neurons. The human ortholog was cloned, and one heterozygous missense mutation without functional analysis was reported (75). The first *NELF* mutation supported by in vitro analysis was reported to cause only KS when a coexistent *FGFR1* mutation was present (20). These findings suggested that digenic disease could be present in some patients (see below). Recently, the first human *NELF* biallelic mutations (with no mutation in any of 12 other IHH/KS genes) were identified in KS

(76). Interestingly, heterozygous *NELF* mutations were only found if there was a heterozygous mutation in a second gene. These findings in mice and humans indicate that NELF plays an important role in mammalian pubertal development (76).

**32.6.1.10 TAC3/TACR3.** Utilizing genome-wide SNP arrays in consanguineous Turkish families with nIHH, linkage was demonstrated to chromosome 4q25. Of the genes within this region, *TACR3*, encoding the GPCR-neurokinin B receptor (NK3R), appeared to be the most likely candidate and homozygous mutations were demonstrated in all affected individuals (77). NK3R is known to be highly expressed in hypothalamic neurons that also express kisspeptin. In other nIHH families, linkage to chromosome 12q13 was observed where the gene *TAC3* encoding the ligand neurokinin B (NKB) was located. Homozygous inactivating mutations were demonstrated in *TAC3* as well (77). Therefore, these studies demonstrated the importance of the neurokinin B system in the regulation of human puberty. Since this study, *TACR3* and *TAC3* mutations were studied in a large cohort of nIHH patients. Biallelic *TACR3* mutations were identified in 5.5% of patients, whereas *TAC3* mutations were rare and found only in two sisters from a consanguineous family (78).

The phenotype of females with *TAC3* and *TACR3* mutations is remarkably similar in that they all had primary amenorrhea and absent breast development (78). In addition, several patients showed spontaneous activity of the HPG axis upon discontinuation of hormonal treatment in adulthood demonstrating a reversible nature of the dysfunction. One patient with homozygous *TAC3* mutations experienced spontaneous puberty and pregnancy, whereas her sister with the same mutation had amenorrhea (78). This reversibility of hypogonadotropic hypogonadism with *TAC3/TACR3* mutations as opposed to the irreversibility of many other gene mutations such as in *KISS1R* is very interesting and requires further study. The exact mechanism of action of NKB and its receptor in mammalian puberty is not yet fully understood. It is postulated that they interact with kisspeptin as they colocalize in the same neurons and their action is expected to regulate release of GnRH from the hypothalamus (78).

**32.6.1.11 GNRH1.** The most obvious candidate gene for mutations in nIHH has been the GnRH ligand (*GNRH1*), particularly because the naturally occurring hypogonadal mouse with an intragenic deletion manifested hypogonadotropic hypogonadism (79), which was rescued by gene therapy with the wild-type *Gnrh1* (80). These studies were performed in 1986, and although a number of small studies in humans subsequently failed to demonstrate *GNRH1* mutations, it was not until 2009 that human mutations were finally discovered. Two different groups found biallelic *GNRH1* mutations in 1/146 (0.7%) (81) and 1/310 (0.3%) (82) nIHH patients, respectively in an autosomal recessive manner. This low prevalence explains

the previous negative studies. One of the more interesting facets of these findings is that GnRH is the first (and only at the time of this writing) hypothalamic releasing factor found to possess mutations in humans—none have been identified in the genes encoding GHRH, CRH, TRH, or somatostatin. These findings suggest that perhaps rarely, mutations will be discovered in these genes as well.

**32.6.1.12 WDR11.** Recently, the *WDR11* gene was identified by positional cloning in a KS patient with a 46,XY,t(10;12)(q26.12;q13.11) balanced chromosomal translocation (8,9). Chromosome 10q26 was hypothesized to represent the most likely region to contain the gene based on phenotypic overlap of IHH/KS compared to those with cytogenetic abnormalities of 10q26. As the breakpoint at 10q26 did not directly disrupt a gene, nearby genes expressed in IHH/KS relevant tissues were tested as positional candidates for mutations (9). Although *FGFR2* represented the most likely candidate based on similarity to known IHH/KS gene *FGFR1*, no mutations were found in this gene or in several others nearby. However, heterozygous missense *WDR11* mutations were identified in ~3% of IHH/KS patients (9).

The protein possesses 12 predicted WD (tryptophan/aspartic acid) domains that form two  $\beta$ -propellers, which are likely to be involved in protein/protein interactions. Confirmation of the human mutations was performed by in silico protein modeling and in vitro studies. Murine *Wdr11* was expressed in the developing olfactory and GnRH migratory pathway and in the adult hypothalamus. In addition, wild-type *WDR11* protein was found to colocalize with EMX1 in vivo and in vitro, and three of the human mutations had impaired EMX1 binding. Zebrafish *wdr11* was expressed throughout the brain at 24 h post-fertilization, which partially overlapped *emx1* expression. This expression was particularly noteworthy in the region of diencephalic GnRH3 neurons at 30–36 h (9). The characterization of human *WDR11* mutations in IHH/KS patients, which were absent in controls and supported by animal studies, and in vitro analysis indicate that *WDR11* likely plays an important role in human puberty. However, the precise function of *WDR11* in puberty will require additional study.

### 32.6.2 Digenic Mutations in IHH/KS

Mutations in more than one gene have been increasingly reported in IHH/KS. In fact, there are at least 12 different combinations described in 18 patients: (1) *PROKR2/KAL1*; (2) *FGFR1/NELF*; (3) *FGFR1/GNRHR*; (4) *FGFR1/FGF8*; (5) *PROK2/PROKR2*; (6) *FGFR1/PROKR2*; (7) *NELF/KAL1*; (8) *NELF/TACR3*; (9) *WDR11/KAL1*; (10) *WDR11/GNRHR*, (11) *KAL1/TACR3*, and (12) the oligogenic pattern of *KAL1/NELF/PROKR2* (83).

Interestingly, for most of these described digenic cases, a mutation in one of the genes would be sufficient to cause IHH/KS based on known inheritance of

monoallelic *FGFR1*, *FGF8*, and *WDR11* (autosomal dominant), monoallelic *KAL1* (X-linked recessive), or biallelic *GNRHR* (autosomal recessive) mutations (83). The prevalence of digenic mutations in IHH/KS has not been extensively reported, as most were reported as single cases. However, one large series in which eight genes (*FGFR1*, *KAL1*, *PROKR2*, *GNRHR*, *FGF8*, *KISS1R*, *NELF* and *PROK2*) were sequenced in 397 IHH/KS patients indicated that digenic disease occurred in 10/88 (11%) of patients who had one known mutation in one gene and 10/397 (2.5%) of all patients (84). When the 13 most common IHH/KS genes (*KAL1*, *GNRHR*, *FGFR1*, *KISS1R*, *TAC3*, *TACR3*, *FGF8*, *PROKR2*, *PROK2*, *CHD7*, *NELF*, *GNRH1*, and *WDR11*) were studied by another group, 6/48 (12.5%) of all IHH/KS patients studied had digenic disease (83). Therefore, most IHH/KS patients appear to have monogenic IHH/KS, given the current number of genes being studied. It has been suspected that digenic gene mutations could cause IHH/KS by synergistic heterozygosity (76). It is certainly feasible that many of the abovementioned genes are likely to function within the same pathway.

### 32.6.3 Adult-Onset Forms of IHH

Mutations in some genes such as the *GNRHR* may result in a phenotype that is mild—adult-onset IHH (see below), while others such as *FGFR1* and *TACR3* may predispose to spontaneous reversal of the phenotype. The female counterpart to male adult-onset IHH is hypothalamic amenorrhea, which is known to be associated with eating disorders, excessive exercise or extreme stress. Recently, a series of 55 females with hypothalamic amenorrhea were studied for mutations in IHH/KS genes, and two had heterozygous *FGFR1* loss-of-function mutations, of which could cause the phenotype (85).

### 32.6.4 Pituitary Causes of Hypogonadism

Mutations in at least seven genes result in impaired pituitary action. Some (*GNRHR*, *LHB*, and *FSHB*) affect only gonadotropin function, whereas the others may affect other pituitary functions (thyroid, adrenal, GH, and prolactin). The molecular basis for those with a known cause is detailed here (Table 32-4).

**32.6.4.1 GNRHR.** The pituitary-expressed GnRH receptor (*GNRHR*) gene represented the first identified gene to be involved in autosomal recessive nIHH in humans (86,87). The *GNRHR* belongs to the GPCR class of receptors, most of which possess an extracellular ligand-binding domain, a seven-transmembrane domain, three extracellular loops, three intracellular loops, and an intracellular carboxy terminal tail (although the *GNRHR* has no C-terminal tail).

To date, all *GNRHR* mutations have been identified in nIHH patients, most of whom have compound

**TABLE 32-4** Gene Mutations Affecting Pituitary Function

Gene	Localization	Phenotype	Inheritance
<i>GNRHR</i>	4q21.2	Normosmic HH	AR
<i>LHB</i>	19q13.3	Isolated LH deficiency	AR
<i>FSHB</i>	11p13	Isolated FSH deficiency	AR
<i>PROP1</i>	5q	CPHD2—short stature, hypothyroid, HH	AR
<i>HESX1</i>	3p21.1–21.2	Septo-optic dysplasia	AR or AD
<i>LHX3</i>	9q34.3	CPHD3	AR
<i>LHX4</i>	1q25	CPHD4	AD
<i>SOX2</i>	3q26.3–q27	Anophthalmia/microphthalmia; CPHD	AD
<i>SOX3</i>	Xq26	CPHD	X-LR

AR = autosomal recessive; AD = autosomal dominant; CPHD = combined pituitary hormone deficiency.

Note that CPHD1 due to *POU1F1* mutations is not shown here as it does not affect gonadotropins.

heterozygous missense mutations (88,89), while intra-genic deletions are uncommon (90). Human *GNRHR* mutations may affect ligand binding, signal transduction or both (88,89). Some *GNRHR* mutations also adversely affect activation of gonadotropin subunit or *Gnrhr* gene promoters in vitro (89). A number of the mutant *GNRHR*s can be rescued in vitro from misfolding and degradation within the cell by the addition of *GNRHR* antagonist IN3 (91).

The prevalence of *GNRHR* gene mutations has been estimated to be 3–5% of all normosmic IHH patients (88,89). Associated somatic anomalies seen with *FGFR1*, *CHD7*, or *KAL1* are uncommon. Of interest, two different missense mutations comprise about half of the reported mutant alleles. These mutations cause either complete IHH (no evidence of puberty) or incomplete IHH (partial evidence of puberty) although some genotypes are associated with mild disease in some families and severe disease in others. *GNRHR* mutations have also been reported to cause constitutional delay of puberty, and may be identified in patients with reversible IHH (88,89).

**32.6.4.2 LHB.** Isolated deficiencies of LH and FSH are exceedingly rare. The pituitary dimeric glycoprotein hormones consist of a common  $\alpha$ -subunit encoded by the chorionic gonadotropin- $\alpha$  (*CGA*) gene and a specific  $\beta$ -subunit gene that confers specificity for the four proteins—hCG, LH, FSH, and TSH. No human *CGA* mutations have been reported, but findings of the KO mouse indicate that the expected phenotype would include nIHH and hypothyroidism due to gonadotropin and TSH deficiency. Homozygous *Cga* KO mice have normal appearing neonatal gonads, but prepubertal adult gonads, which suggests that gonadotropins are not necessary for prenatal sexual differentiation (92).

The *LHB/CGB* gene complex in humans consists of six *CGB* genes with one *LHB* gene, which are highly homologous but polymorphic. However, there have only been several human *LHB* mutations, which are inherited in an autosomal recessive manner. At least five males have now been reported and all had small testes, oligospermia, and low testosterone (93). The first reported patient with an *LHB* mutation had elevated immunoreactive, but reduced biologically active, serum LH levels (94), whereas the others had low/undetectable LH levels and measurable to elevated FSH levels. Two reported females with *LHB* mutations demonstrated normal pubertal development probably because of normal FSH secretion, but became amenorrheic and had low LH with elevated FSH levels (93). It is likely that *CGB* mutations could be lethal in humans as placental production would be predicted to be deficient.

**32.6.4.3 FSHB.** Mutations in *FSHB* have been described in autosomal recessive isolated FSH deficiency (95,96). All mutations studied have been shown in vitro to result in low immunoreactive and low bioactive FSH levels (95,97,98). Most females completely lack sexual development, but some have had incomplete breast development. All females have presented with primary amenorrhea with low serum estradiol levels, very low or unmeasurable serum FSH, and elevated LH levels. This endocrinologic profile indicates that in the face of hypogonadism, GnRH appropriately rises and stimulates LH, which results in elevated serum LH levels. However, as there is an *FSHB* mutation, dimeric FSH is reduced, resulting in isolated FSH deficiency. Several males with *FSHB* mutations have had either normal pubertal development or delayed puberty, but all have been azoospermic.

Females with isolated FSH deficiency have elevated serum LH and exaggerated LH pulses, but somewhat surprisingly, they do not exhibit hirsutism or hyperandrogenism (99,100). Women with PCOS, who have similar LH pulses and elevated LH/FSH ratios, demonstrate hyperandrogenism. These findings challenge the tenants of the two-gonadotropin two-cell hypothesis, which states that LH stimulates ovarian thecal cells to produce androgens, which serve as precursors for estrogens in granulosa cells where FSH induces aromatization to estrogens (99,100). In fact, one woman with isolated FSH deficiency only had a rise in serum testosterone level after FSH followed by LH administration (not LH alone). The fact that isolated FSH deficiency is associated with low androgens suggests that FSH could play an important role in ovarian androgen production, perhaps by increasing LH receptors, or by inducing CYP17 enzyme activity (an androgen dependent enzyme), inhibin, or growth factors (99,100). Ovarian follicles typically show primordial, primary, and antral follicles, and normal fertility may be restored with FSH treatment.

### 32.6.5 Combined Pituitary Hormone Deficiency

CPHD is defined as the deficiency of GH plus at least one additional pituitary hormone (ACTH, TSH, prolactin, FSH, or LH). Mendelian Inheritance in Man (MIM) lists CPHD1 (MIM 613038), CPHD2 (MIM 262600), CPHD3 (MIM 221750), and CPHD4 (MIM 262700); and all except CPHD1 (*POU1F1*) affect gonadotropins. If all pituitary hormones are deficient, the patient has panhypopituitarism, which may be fatal unless treated, especially because of subsequent adrenal insufficiency. If this CPHD is congenital, the patient should display extremely short stature due to deficiency of TSH and GH. The genetic basis for forms of CPHD that affect the reproductive axis is now discussed (Table 32-5).

**32.6.5.1 *PROP1* (CPHD2).** Mutations in pituitary transcription factors have been shown to cause isolated hypogonadotropic hypogonadism in association with deficiencies of other pituitary hormones. *PROP1* is important for early pituitary development as mutations of *PROP1* result in CPHD in humans. *PROP1*-deficient patients have an autosomal recessive form of TSH, GH, prolactin, and gonadotropin deficiency (101,102). Affected individuals manifest extremely short stature secondary to deficient TSH and GH levels and may have a reduced ability of their pituitary to respond to the corresponding releasing factors. Many different mutations have been characterized including missense mutations and small deletions (101,102) and mutations of the mouse ortholog—*Prop1*—cause a similar phenotype in the Ames dwarf mouse. *PROP1* mutations are

rare in IHH patients without failure of other pituitary hormones.

**32.6.5.2 *HESX1*.** Homozygous and heterozygous mutations in *HESX1*, which encodes a transcription factor, have been identified in families with affected individuals with septo-optic dysplasia, a disorder characterized by panhypopituitarism, optic nerve atrophy, and other midline CNS abnormalities including agenesis of the corpus callosum and septum pellucidum (Table 32-5) (104,105). The mouse ortholog (*Hesx1*) is expressed in early development of the forebrain. Later, *Hesx1* expression is restricted to Rathke's pouch, which ultimately becomes the anterior pituitary gland. Since panhypopituitarism occurs, IHH is a common feature of septo-optic dysplasia.

**32.6.5.3 *LHX3* (CPHD3) and *LHX4* (CPHD4).** Two other genes contribute to the pathophysiology of autosomal CPHD. *LHX3* mutations cause autosomal recessive CPHD (106), whereas *LHX4* mutations cause an autosomal dominant form. The phenotype of patients with *LHX3* mutations consists of severe growth retardation (secondary to GH and TSH deficiency) and hypogonadotropic hypogonadism. All pituitary hormones (GH, TSH, prolactin, FSH, and LH) except ACTH may be deficient (106). Interestingly, there is severe restriction of cervical spine rotation, which results in elevation and anteversion of the shoulders similar to what is seen with mutation in the mouse ortholog. Although a family with TSH, GH, and ACTH deficiency due to a heterozygous *LHX4* mutation has been described, the child was prepubertal, so gonadotropin levels were not investigated (107). *LHX4* should also result in gonadotropin

**TABLE 32-5 Single-Gene Disorders in Hypergonadotropic Hypogonadism in Females**

Gene	Localization	Phenotype	Inheritance
<i>SRY</i>	Yp11.3	Swyer syndrome (genetic males)	Sporadic, Y-linked
<i>POF1</i>	Xq26q28	Ovarian failure (F)	Sporadic or XLD
<i>POF2</i>	Xq13.3–q22	Ovarian failure (F)	Sporadic; or XLD
<i>DIAPH2</i>	Xq22	Ovarian failure (F)	Disruption in X-auto-some translocation
<i>FMR1</i>	Xq27.3	Fragile X syndrome (M); ovarian failure (F)	XLD
<i>BMP15</i>	Xp11.2	Ovarian failure (F)	XLR
<i>FSHR</i>	2p21p16	Primary amenorrhea (F); oligospermia (M)	AR
<i>AIRE</i>	21q22.3	APECED	AR
<i>POF3 (FOXL2)</i>	3q23	BPES (M & F); with ovarian failure (M)	AD
<i>NOBOX</i>	7q35	Ovarian failure	AD, sporadic
<i>FIGLA</i>	2p12	Ovarian failure	Sporadic; possible AD
<i>NR5A1</i>	9q33	Adrenal failure/sex reversal (M); POF (F)	AR or AD
<i>GALT</i>	9p13	Galactosemia (with ovarian failure)	AR
<i>EIFB2</i>	14q24	Ovarioleukodystrophy	AR
<i>EIFB4</i>	2p23.3	Ovarioleukodystrophy	AR
<i>EIFB5</i>	3q27	Ovarioleukodystrophy	AR
<i>CYP17A1</i>	10q24.3	17-hydroxylase deficiency	AR
<i>CYP19A1</i>	15q21.1	Aromatase deficiency	AR

XLD = X-linked dominant; XLR = X-linked recessive; AR = autosomal recessive; AD = autosomal dominant.

LHR mutations can also cause gonadal failure in males with varying degrees of sexual ambiguity; in females, it causes anovulation and is included in Table 32-6.

deficiency, and this was recently described as affected children were followed into pubertal age (108,109).

**32.6.5.4 SOX2 and SOX3.** Mutations in *SOX2* and *SOX3*, both of which are high-mobility group (HMG) box transcription factors, have been described in humans with hypogonadotropic hypogonadism. Heterozygous de novo *SOX2* mutations were identified in patients with developmental delay, bilateral anophthalmia or microphthalmia, short stature, and male genital tract abnormalities. Recently, mice heterozygous for a targeted *Sox2* disruption did not have eye defects, but did demonstrate abnormal anterior pituitary development with GH, TSH, and LH deficiency (110). In a large series of patients with “congenital hypothalamic-pituitary disorders,” 8/235 (3.4%) had heterozygous *SOX2* sequence variations, most of which were de novo (110). Mutations were nonsense, frameshift deletions/insertions, or missense mutations that impaired function (DNA binding, nuclear translocation, or transactivation). Patients with *SOX2* mutations had eye defects, along with anterior pituitary hypofunction including IHH. However, additional defects of the corpus callosum, hypothalamic hamartomas, sensorineural hearing loss, and esophageal atresia were also observed (110). These findings in both mouse and human suggest that *SOX2* is necessary for normal reproductive development and function.

*SOX3* mutations cause an X-linked recessive form of pituitary deficiency. Several *SOX3* mutations have been reported, the first being an in-frame 33-bp duplication in a family with X-linked mental retardation, facial abnormalities, and GH deficiency (111). Another ~686 kb duplication was identified in two siblings with variable degrees of hypopituitarism, corpus callosum abnormalities, anterior pituitary hypoplasia, an ectopic posterior pituitary, and an absent infundibulum (112). Mental retardation, however, was not present in these siblings. Corroborative findings have been identified in mice with targeted deletion of *SOX3*. The phenotype consisted of impaired pituitary development and midline structures, and these pituitary and hypothalamic defects persisted postnatally (113).

## 32.7 HYPERGONADOTROPIC HYPOGONADISM

Women with hypergonadotropic hypogonadism may either have a normal 46,XX karyotype or have aneuploidy or a structurally abnormal X chromosome (Table 32-5). Not unexpectedly, the greatest risk for a chromosome abnormality is for females with primary amenorrhea, rather than those with secondary amenorrhea. The results from several very large clinical studies of women with primary and secondary amenorrhea are shown in Table 32-2 (6,7). More than two-thirds of females with primary amenorrhea had a karyotypic abnormality vs ~1% of women with secondary amenorrhea (6–7).

### 32.7.1 X Chromosome Abnormalities

Females completely lacking an X chromosome include those with pure 45,X karyotypes as well as those with another cell line (46,XY, 46,XX, 47,XXX, or 46,X iXq). About 90% of females with a 45,X cell line with or without mosaicism present with primary amenorrhea, the complete lack of sexual development, and irreversible ovarian failure (6,114). About 5–10% of 45,X females have normal puberty and menarche, but these menses are usually short-lived and often cease before age 40. Women with a 45,X cell line who menstruate may be fertile, but reproductive loss may occur in the form of spontaneous abortions, stillbirths, and chromosomal abnormalities (including 45,X and Down syndrome) and is common (114). Patients with a 45,X cell line (Turner syndrome) manifest phenotypic features such as short stature, widely spaced nipples, webbed neck, shield chest, multiple skin nevi, and a short fourth metacarpal. However, the most consistent feature is short stature with heights under 5 ft. The most serious associated somatic anomalies include cardiac (in about 50%) and renal abnormalities (114). A dilated aorta has a several percentage estimated chance of rupturing during pregnancy, suggesting that donor egg in vitro fertilization should be discouraged (115). If there is a coexistent Y chromosome with a 45,X cell line, gonadoblastomas may occur within the streak gonads, which may give rise to more serious germ cell tumors. Therefore, the gonads should be removed in these patients with a Y cell line.

Individuals with a 45,X/46,XY karyotype may manifest any of several different phenotypes. If bilateral abdominal streak gonads are present, the phenotype resembles other 45,X females who do not have a Y cell line with short stature, absent breast development, but with an intact vagina and Müllerian system. If an intra-abdominal streak and a contralateral testis either in the abdomen or in the labioscrotum are present, sexual ambiguity will result. Much less commonly, 45,X/46,XY patients have bilateral scrotal testes, which renders them a male phenotype (116).

Turner syndrome is thought to result from haploinsufficiency of multiple genes on the X chromosome that affect embryologic development, stature, and ovarian function. The short stature likely results from the deletion of one allele of *SHOX* (short stature homeobox gene), a transcription factor on Xp22 that is primarily expressed in osteogenic cells (117). Similarly, patients with idiopathic short stature (without Turner syndrome) may harbor mutations in *SHOX*. The phenotype of patients possessing *SHOX* mutations varies depending upon the mutation type—either Langer mesomelic dysplasia resulting from deletions or Leri-Weill dyschondrosteosis, a skeletal dysplasia with disproportionate short stature, mesomelic limbs, and the Madelung deformity (a radial bone anomaly also sometimes seen in Turner syndrome) caused by nonsense mutations (117,118).

Partial deletions of the X chromosome may also impair ovarian function. In general, deletions affecting Xp11 result in ovarian failure in about half of the patients, while the other half have menstrual function (119). Even if menstrual function is normal, fertility is typically impaired. With more distal deletions, such as at Xp21, the phenotype is usually less severe. Most women with Xp deletions are short, regardless of ovarian function, further supporting that other statural determinant genes could reside within these regions. Several families with Xp deletions have also been reported (119).

Deletions of Xq may also result in ovarian failure. Similar to Xp deletions, proximal Xq (such as Xq13) deletions are usually more severe, and these patients have absent breast development, primary amenorrhea, and gonadal failure. If the deletion involves more distal Xq, menarche may occur with or without ovarian failure. Familial forms of Xq deletions manifesting as ovarian failure have also been reported. The mechanism of ovarian failure in patients with X chromosome abnormalities has not been clearly elucidated, but could involve a dosage phenomenon, especially if the involved gene/genes do not escape X-inactivation. Deleted/disrupted ovarian determinant genes probably increase follicular atresia of the ovary similar to that seen in patients deleted of an entire X chromosome. It is also possible that the Xq deletion contains genes that might affect mitosis or meiosis, which could result in enhanced follicular atresia (see specific genes below). Chromosomal rearrangements involving the X chromosome have also been reported to disrupt ovarian gene function (119).

### 32.7.2 Y Chromosome Disorder—Swyer Syndrome

Although patients with Swyer syndrome have a pure 46,XY cell line, their phenotype is that of a sexually delayed female. These patients will have bilateral streak gonads, normal stature, and a normal uterus and vagina without sexual ambiguity. They appear to have the highest risk of developing tumors in their dysgenetic gonads (up to 25%); therefore, extirpation of the gonads should be performed after the diagnosis (120).

The gene for the sex-determining region of the Y chromosome (*SRY*) resides on distal Yp. When *SRY* is present, the undifferentiated gonad will develop into a testis, which will elaborate anti-Müllerian hormone (AMH) to remove the Müllerian system, followed by the secretion of testosterone for sexual differentiation. In Swyer syndrome patients, the gonad is dysfunctional (and replaced by fibrous streaks), so that AMH and testosterone are not produced. The lack of AMH leads to the retention of the Müllerian system, while the reduction in normal Leydig cell function results in low testosterone and absent male sexual development. Therefore, the patient presents as a phenotypic female without breast development. Most cases of Swyer syndrome are sporadic and only about

15% are caused by *SRY* mutations, which is a single-exon gene encoding a transcription factor with a conserved HMG domain. Therefore, other yet to be discovered genes must be involved in the pathogenesis (120,121). Other genes may cause disorders of sexual development resulting in sexual ambiguity, but they will be covered elsewhere. Swyer syndrome is included here because it results in gonadal failure in phenotypic females.

### 32.7.3 46,XX Ovarian Failure

Women with hypergonadotropic hypogonadism are said to have premature ovarian failure (POF) when this occurs in about 1% of women before age 40. Ovarian function may wax and wane; and pregnancy may occasionally occur spontaneously. These patients may sometimes bleed when the progestin withdrawal test is performed if there is some residual ovarian function. This has prompted some investigators to suggest that it should be called hypergonadotropic amenorrhea or primary ovarian insufficiency (122). Nevertheless, most patients with hypergonadotropic hypogonadism demonstrate ovarian failure. For practical purposes, the molecular basis for most patients with amenorrhea, elevated gonadotropins on two occasions, and a 46,XX karyotype is unknown if known causes such as pelvic radiation, chemotherapy, or surgical extirpation are excluded. Clinical studies have suggested that many of these women may have an autoimmune basis for their hypogonadism as other associated endocrinopathies such as hypothyroidism, adrenal insufficiency, and diabetes may be present. However, a small percentage of patients have been found to have single-gene disorders (see below) (122).

### 32.7.4 Single-Gene Disorders Causing Ovarian Failure and Infertility

The Xq13–Xq26 region has been previously suggested to contain ovarian determinant genes, but surprisingly few have been identified. On the basis of these findings, the Xq26–q28 region has been designated POF1, whereas Xq13.3–q21.1 has been identified as POF2. As detailed in MIM, there are currently eight forms of POF—POF1 (MIM 311360); POF2A (MIM 300511); POF2B (MIM 300604); POF3 (MIM 608996); POF4 (300510); POF5 (MIM 611548); POF6 (MIM 612310); and POF7 (MIM 612964). The *FMR1* gene, which causes fragile X syndrome, resides within POF1 region, whereas *DIAHP2* and *POF1B* genes reside within the POF2 region. The POF3–POF7 regions are found on autosomes (except POF4, which is located on the X chromosome) and contain genes possessing human mutations backed by functional studies (Table 32-5). The X chromosome genes will first be reviewed followed by the autosomal genes. If the gene is relevant to males, this will only be briefly mentioned as this will be covered elsewhere.

### 32.7.5 Single-Gene Disorders of the X Chromosome Associated with Ovarian Failure

The prevalence of mutations in known genes for patients with 46,XX ovarian failure except fragile X syndrome is rare. Nevertheless, even rare-mutation-containing genes can provide insight into mechanisms of disease.

### 32.7.6 Diaphanous 2 (*DIAPH2*) within the POF2 Region

*DIAPH2* was the first gene suggested to be an ovarian determinant gene. A woman with POF had a balanced t(X;12)(q21;p1.3) that appeared to disrupt diaphanous 2 (*DIAPH2*) gene. However, the importance of this gene remains speculative as no point mutations have yet been described (123). Disruption of *DIAPH2* was proposed to be causative in this patient as this gene has high homology to *dia* in *Drosophila*, which is expressed in the testes and ovary, and results in sterility when mutated (123). Of interest, the other gene within this region (*POF1B*) has not conclusively been shown to possess mutations that are not seen in controls with normal ovarian function.

### 32.7.7 *FMR1* within the POF1 Region

Fragile X syndrome is the most frequently recognized single-gene disorder that includes POF. Fragile X syndrome is an X-linked dominant disorder with incomplete penetrance characterized by large ears and jaws, varying degrees of mental deficiency, and macro-orchidism in affected males. The mental deficiency may be extremely variable being subtle or manifested solely as autism. *FMR1* resides at a fragile site of Xq27 (POF1 region) and contains a triplet repeat of CGG nucleotides ranging from 6 to 50 copies in unaffected individuals. Affected males have a full expansion to  $\geq 200$  repeats, while carrier females have 50–200 repeats (the premutation allele). Premutation alleles are unstable and may expand in meiosis in carrier females such that the full expansion results, which gives rise to an affected male. Some females who possess premutation alleles may also manifest a mild degree of mental deficiency or a learning disability.

Fragile X males have macro-orchidism and normal testicular histology, but ~15% of females with premutation alleles ascertained through fragile X families may have POF (124). If large cohorts of females with POF are analyzed (rather than Fragile X families), the risk of carrying the *FMR1* premutation allele is approximately 3–4% if there are no other family members with POF, but up to 12–15% if there are at least two affected females within the family (125). It is interesting that no women with full *FMR1* mutations had POF—it was only the carrier females. The fragile X full mutation is a

null allele with impaired methylation and protein inactivation. However, the premutation allele is associated with mRNA overexpression, and has been found to be expressed in the ovary. These considerations must be taken into account when genetic counseling is provided to women with POF who possess an *FMR1* premutation allele. Should pregnancy occur, half of her sons will have fragile X syndrome and half of her daughters will be carriers. Even if the identified premutation carrier female does not conceive, other family members could potentially be carriers and be at risk for fragile X syndrome. It is also known that males with premutation alleles could later manifest an adult-onset tremor ataxia syndrome (122).

### 32.7.8 Bone Morphogenetic Protein-15 (*BMP15*) Gene in POF4

*BMP15* mutations were first described in a family with two young women (ages 23 and 18), who had primary amenorrhea, hypoplastic ovaries, and elevated gonadotropin levels. A heterozygous missense *BMP15* mutation was identified in both of the affected females transmitted from the father. The mutation was not observed in 210 controls, and in vitro analysis supported a functional effect upon protein action (abnormal processing, impaired granulosa cell growth, and antagonism of wild-type *BMP15* stimulated granulosa cell growth) (126). Subsequent studies of large cohorts of POF women suggest that the prevalence of *BMP15* mutations is <1% (127). Most mutations are missense mutations, which appear to impair secretion.

### 32.7.9 Single-Gene Disorders of the Autosomes Associated with Ovarian Failure

Interestingly, some of the autosomal genes possessing mutations in POF women, which were identified before POF 3, 5, 6 and 7, are not designated in such a manner in MIM. Known human autosomal genes resulting in ovarian failure are discussed.

**32.7.9.1 Follicle Stimulating Hormone Receptor (*FSHR*).** *FSHR* gene mutations have been identified to cause autosomal recessive POF (128). The FSH ligand binds to this heptohelical GPCR located on the cell surface of ovarian granulosa cells, which then results in estradiol production. Most affected females described present with primary amenorrhea, and about half have breast development, while the others have not initiated thelarche. Some of the women with normal breast development may have menstrual periods before becoming amenorrheic and hypogonadal. Ovarian follicles range from primordial to mature, indicating that the defect is not as severe as mutations of the *FSHB* ligand (see *FSHB* gene in pituitary disorders). Interestingly, males with *FSHR* mutations are fertile. Identified *FSHR* mutations

may affect binding, signal transduction, or both. Mutations of the other gonadotropin (LH) receptor (*LHR*) usually cause anovulation in females (and are discussed under eugonadism).

**32.7.9.2 Autoimmune Regulator (*AIRE*).** The autoimmune polyglandular syndrome type 1, also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), is an autosomal recessive multisystem autoimmune disease. APECED is more frequent in Finnish individuals and Iranian Jews. Moniliasis is a common initial presenting feature in over half of the patients, but can occur at anytime. Hypoparathyroidism (80%) and adrenal failure (70%) are the most frequent endocrinopathies of the disorder, but ovarian failure (60%) and testicular failure (14%) may also occur (129,130).

Mutations in the *AIRE* (autoimmune regulator) gene, which encodes a transcriptional factor with two PHD-type zinc-finger motifs, have been identified in APECED patients (129,130). The elucidation and characterization of *AIRE* mutations represented the first instance of a single-gene defect causing systemic autoimmune disease in humans. Approximately 80% of *AIRE* mutations in Finnish patients consist of a single nonsense mutation (Arg257X), while a 13-bp deletion accounts for over half of the mutations in North American patients. A single nonsense mutation (Arg139X) occurs in about 80% of Sardinian *AIRE* alleles (129,130). Currently, it is not clear whether specific mutations increase the likelihood of ovarian failure vs other endocrinopathies.

**32.7.9.3 Forkhead Transcription Factor (*FOXL2*) in POF3.** In a fascinating biological phenomenon, a syndrome comprised of blepharophimosis (narrowing of horizontal opening of the eyelids), ptosis, and epicanthus inversus syndrome (BPES) may include POF (BPES type I) or not (BPES type II). In both types of diseases, which are inherited in an autosomal dominant manner, heterozygous *FOXL2* mutations have been identified. Why mutations of this gene affect eye lid development and normal ovarian function, while sparing testicular function (gonadal failure is sex-limited) is perplexing. Most patients with type-I and -II BPES have mutations in one of the two hotspots of the *FOXL2* gene on chromosome 3q23 (131). Thirty percentage of mutations lead to polyalanine expansions and 13% consist of frameshift duplications. The prevalence of *FOXL2* mutations in isolated POF without BPES is likely to be rare, but has been described (132).

**32.7.9.4 Newborn Ovary Homeobox, Mouse, Homolog of (*NOBOX*).** *NOBOX* is a homeobox gene localized to chromosome 7q35 expressed predominantly in the ovary and testis. Of interest, *Nobox* KO male mice were fertile, but females had atrophic ovaries. *Nobox* is preferentially expressed in the oocyte and has a role in folliculogenesis and regulation of oocyte-specific genes in the mouse. One of the 96 Caucasian POF patients had a heterozygous missense mutation not present in 278 ethnically matched controls. Its role in POF is currently unclear, but is probably uncommon (133).

**32.7.9.5 Factor in Germline Alpha (*FIGLA*) in POF6.** Two of the 100 Chinese POF women were recently described to possess small deletions (3bp and 22bp) in the *FIGLA* gene on chromosome 2p12 that were absent in 340 female controls with regular menses and no history of infertility (134). *FIGLA* encodes a germ-cell-specific transcription factor, which regulates expression of genes in the oocyte. Both women with the mutations had secondary amenorrhea and hypergonadotropic hypogonadism. One of these deletions disrupted *FIGLA* binding to the TCF3 helix-loop-helix domain, while the other resulted in a frameshift (134).

**32.7.9.6 Nuclear Receptor Subfamily 5, Group A, Member 1 (*NR5A1*) in POF7.** SF1 is a vital transcription factor regulating steroidogenesis in the gonad and adrenal glands. It is encoded by the *NR5A1* gene, which has been known as *FTZF1*. Similar to the targeted disruption of the mouse ortholog, a mutation in the *NR5A1* gene caused undermasculinization of 46,XY males and adrenal failure (135). However, *NR5A1* mutations are now known to cause a wide range of disorders of sexual differentiation with and without adrenal failure that may be inherited as autosomal recessive or autosomal dominant traits (136).

The phenotype in genetic females was predicted to consist of adrenal failure and delayed puberty with absent breast development and primary amenorrhea, with elevated serum gonadotropins. It does now appear that mutations do cause 46,XX ovarian failure with or without adrenal failure. Interestingly, these individuals with POF can be noted in families with affected males. In fact, two of 25 (8%) POF women with normal adrenal function were found to harbor heterozygous *NR5A1* mutations consistent with autosomal dominant inheritance (136).

**32.7.9.7 Galactose-1-Phosphate Uridyltransferase (*GALT*).** Galactosemia is an autosomal recessive disease in which galactose cannot be properly metabolized to glucose. The phenotype usually consists of failure to thrive, nausea, vomiting, hepatomegaly, cataracts, mental retardation, speech abnormalities, and hemolytic anemia. If treated by a galactose-free diet, the prognosis for liver function and mental capacity is improved but not to the normal level. Several different enzymes are involved in galactosemia, but *GALT* mutations have been shown to have a sex-specific effect upon reproduction in that females, but not males, develop gonadal failure (119). The enzyme encoded by *GALT* converts galactose-1-phosphate and UDP-glucose to UDP-galactose and glucose-1-phosphate.

About two-thirds of women with galactosemia had POF, while none of the eight men had testicular failure (137). These females had normal pubertal development, but half presented with primary amenorrhea, and the remainder had secondary amenorrhea. However, LH and FSH levels were elevated in both groups. The precise etiology of ovarian failure in galactosemia is unknown, but a detrimental metabolic developmental defect could be caused by galactose-1-phosphate or by abnormal

glycosylation of gonadotropin glycoproteins or their receptors. More than several hundred *GALT* mutations have been described, many of which are missense mutations. Heterozygotes do not develop gonadal failure. Interestingly, the *Galt* KO mouse has a less-severe phenotype, with no gonadal developmental defect or dysfunction (138).

### 32.7.10 Eukaryotic Translation Initiation Factors 2, 4, and 5

Leukoencephalopathy with vanishing white matter is caused by mutations in any of the five subunits of the translation initiation factor eIF2B. It has also been reported that patients with leukoencephalopathy with vanishing white matter and ovarian failure (also known as ovarioleukodystrophy) may possess mutations in three of the subunits (2, 4, or 5) (139). All are inherited in an autosomal recessive manner. Females may present with primary or secondary amenorrhea, elevated levels of serum gonadotropins, and a variety of neurologic abnormalities including gait and speech problems, spasticity, the need for a walker, dysarthria, optic atrophy, and reduced cognitive function. When 93 women with isolated POF (and no neurologic abnormalities) were screened for mutations in the *EIF2B2* gene, none were identified, suggesting that they are not a common cause of POF (139).

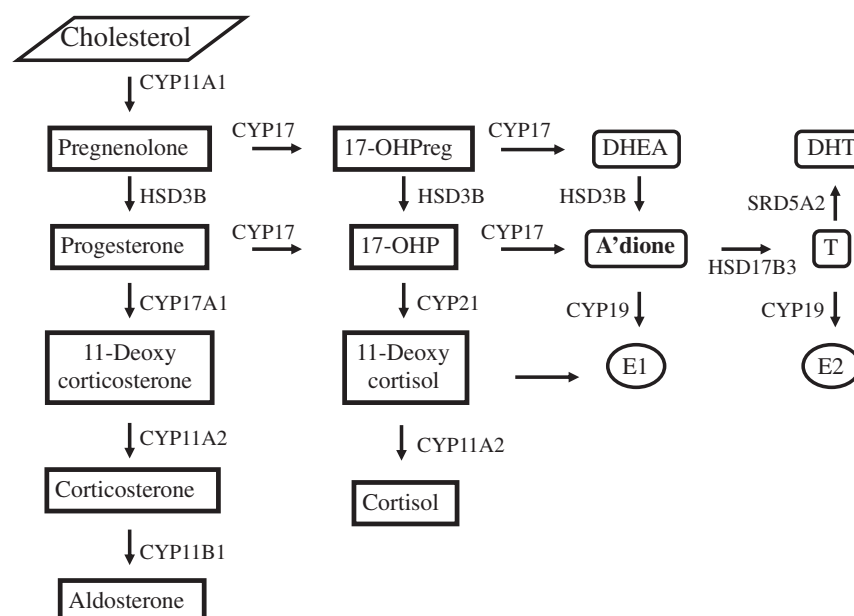

### 32.7.11 Genes in Steroid Enzyme Pathway that Result in Gonadal Failure

The biochemical pathway utilizes 27-carbon cholesterol as a precursor for the production of sex steroids, adrenal

mineralocorticoids, and glucocorticoids (Figure 32-3). Mutations in some of these enzymes cause disorders affecting both adrenal function and disorders of sexual development (congenital adrenal hyperplasia); but these are not discussed here. However, selected genes of the steroid enzyme pathway, which may result in gonadal failure in females, are discussed.

**32.7.11.1 Cytochrome P450, Family 17, Subfamily A, Polypeptide 1 (*CYP17A1*) Gene.** Cytochrome P450, encoded by *CYP17A1*, is an enzyme with at least two functions: (1) 17-hydroxylase activity (converting progesterone to 17-hydroxyprogesterone and pregnenolone to 17-hydroxypregnenolone) and (2) 17–20 desmolase activity (converting 17-hydroxypregnenolone to dehydroepiandrosterone [DHEA] and 17-hydroxyprogesterone to androstenedione) (140). *CYP17A1* mutations cause an autosomal recessive deficiency in the production of androgens, progestins, and estrogens. Cortisol is deficient as it is derived from 17-hydroxyprogesterone, but mineralocorticoids such as 11-deoxycorticosterone and corticosterone may be elevated, with associated hypertension and hypokalemic alkalosis (Figure 32-3).

The phenotype of *CYP17* deficiency in 46,XX females includes delayed puberty with absent breast development, primary amenorrhea, and elevated gonadotropins. The vagina, uterus, and ovaries are present, but they are prepubertal. 46,XY males have a similar phenotype to females except that they will not have a uterus or upper vagina as AMH is elaborated from their normal testes. Some males with partial deficiency may have sexual ambiguity. A variety of mutations in *CYP17* have been described, consisting predominantly of deletions and insertions (140).

**FIGURE 32-3** The steroid enzyme pathway is shown. The steroids are indicated within boxes while the enzymes are shown adjacent to arrows. E1 = estrone; E2 = estradiol; A'dione = androstenedione; T = testosterone; DHT = dihydrotestosterone; 17OHP = 17-hydroxyprogesterone. Relevant mutations—*CYP17A1* and *CYP19A1*—are discussed in the text.

**32.7.11.2 Cytochrome P450, Family 19, Subfamily A, Polypeptide 1 (CYP19A1) Gene Encoding Aromatase.** Although rare, mutations in *CYP19A1*, which encodes for the cytochrome P450 enzyme aromatase, cause autosomal recessive aromatase deficiency. Affected females with aromatase deficiency cannot convert the androgens (testosterone and androstenedione) to the estrogens (estradiol and estrone), respectively (141). At birth, females have sexual ambiguity with clitoromegaly, but because they have ovaries, they do not demonstrate labioscrotal gonads. When these children approach pubertal age, FSH rises, and multicystic ovaries develop (141). However, the increased FSH cannot elicit the production of sufficient ovarian estradiol so that breast development and menstruation do not occur. Serum LH levels are also usually elevated in affected patients.

An interesting effect of *CYP19A1* mutations is that the heterozygous mother carrying an affected female fetus can also develop hyperandrogenism and hirsutism (141). This occurs because the fetal placenta (derived from the fetus and with the same genotype as the fetus) cannot adequately convert androgens to estrogens. Normally, the placenta has quite robust aromatase activity, which serves to protect the mother from hyperandrogenemia.

### 32.7.12 Eugonadal Causes of Infertility

Most women with menstrual disorders are eugonadal. Genetic aspects of eugonadal infertility are now discussed (Table 32-6). These have been divided into those with non-obstructive eugonadism, which is discussed first, and obstruction.

### 32.7.13 Polycystic Ovary Syndrome

PCOS is the most common cause of anovulation, comprising more than two-thirds of all ovulation disorders affecting about 5–8% of all women (142). In general, PCOS is defined as hyperandrogenic anovulation with or without polycystic-appearing ovaries on ultrasound (143,144). The phenotype of PCOS women includes menstrual abnormalities (amenorrhea, oligomenorrhea, and/or menometrorrhagia), variable degrees hirsutism or elevated androgens (testosterone and/or dehydroepiandrosterone sulfate), obesity, and hyperinsulinemia with an increased risk for developing type-2 diabetes mellitus. These patients may have hypercholesterolemia and hypertriglyceridemia. The combination of hypertension, increased waist/hip ratio, impaired glucose tolerance, and hyperlipidemia comprise the metabolic syndrome, which has profound risks for future cardiovascular disease (142).

The pathophysiology of PCOS is quite complex and not well understood, but chronic anovulation results. In PCOS, tonic (rather than cyclic) estrogen production is present, which fails to elicit regular LH surges. Instead of an increased estradiol (E2)/estrone (E1) ratio, PCOS

is characterized by a reduced E2/E1 ratio. Sex-hormone-binding globulin (SHBG) is also reduced in PCOS, and several factors may contribute to this—hyperandrogenemia, hyperinsulinemia, and obesity (because about three-quarters of PCOS women are obese). Decreased SHBG results in increased free estrogens and androgens. The unopposed estrogen stimulation of the endometrium increases the risk of endometrial cancer (142). The increased free estrogens tonically stimulate LH further inciting hyperandrogenemia, which results in follicular atresia and the clinical signs and symptoms of hirsutism. Insulin also increases the production of androgens, further exacerbating hirsutism and predisposing to diabetes (142).

The pathophysiology and the molecular basis of PCOS are currently unknown. Evidence suggests that PCOS is a complex disease, which has largely been investigated through the use of association studies (145). Genes including insulin (*INS*), the insulin receptor (*INSR*), steroid enzymes, and follistatin (*FST*) have been implicated,

**TABLE 32-6 Gene Mutations in Eugonadism**

Gene	Localization	Phenotype	Inheritance
<i>Non-Obstructive Infertility</i>			
<i>POMC</i>	2p23.3	PCOS-strong association/multiple comparisons	Association only
<i>FBN3</i>	19p13	PCOS-strong association/multiple comparisons	Association only
<i>ACVR2A</i>	2q22.2–q23.3	PCOS	Association only
<i>FEM1B</i>	5q23.1	PCOS	Association only
<i>SGTA</i>	19p13	PCOS	Association only
<i>LHR</i>	2p21	Anovulation (F); undermasculinization (M) <sup>a</sup>	AR
<i>NFE2L3</i>	7p15	Endometriosis	Association only
<i>HOXA10</i>	7p15	Endometriosis	Association only
<i>HOXA13</i>	7p15–p14.2	Hand–foot–uterus syndrome (also hypospadias in males)	AD
<i>Obstructive Infertility</i>			
<i>AR</i> <sup>a</sup>	Xq11q12	Complete androgen insensitivity syndrome (M)	XLR
<i>WNT4</i>	1p35	Müllerian aplasia & hyperandrogenism	Sporadic, possible AD
<i>HNF1B</i>	17q12	MODY & Müllerian aplasia	AD

<sup>a</sup>Incomplete forms cause sexual ambiguity in males (not discussed here). XLR = X-linked recessive; AR = autosomal recessive; AD = autosomal dominant; YL = Y-linked.

but currently, a causative molecular defect is unknown. More recent evidence suggests the most significant association of PCOS is with fibrillin 3 (*FBN3*) on chromosome 19p13.2 and POMC on chromosome on 2p23.3 with lesser degrees to several other genes (Table 32-6), but causative mechanisms have not been determined (145).

### 32.7.14 Luteinizing Hormone Receptor Gene

A very rare cause of anovulation is the mutation of the gene for the LH receptor (*LHR*), a GPCR expressed in the thecal cells of the ovary and the Leydig cells of the testis. The phenotype of patients with *LHR* gene mutations depends on the karyotype (146–148). Genetic females with *LHR* gene mutations develop normal puberty and have menarche. However, they then become anovulatory with usually elevated (or normal) levels of LH and FSH (146–148).

46,XY males with severe, loss-of-function *LHR* mutations also usually present as phenotypic females, but they have absent breast development and can demonstrate normal appearing external genitalia except they have a blind vaginal pouch (146). As the testes are normal and produce AMH, no uterus or vagina is present. Therefore, these patients will appear as phenotypic females with no breast development. Depending on the severity of the *LHR* mutation, the external genitalia ranges from normal appearing female (severe mutations) to sexual ambiguity to bilaterally descended testes (mild mutations). Serum gonadotropins are usually elevated, and the testes are small and devoid of Leydig cells. Inactivating *LHR* mutations are inherited in an autosomal recessive manner, in contrast to activating *LHR* mutations, which cause autosomal dominant familial male precocious puberty.

### 32.7.15 Endometriosis

Endometriosis can be a debilitating disease estimated to affect 8–10% of reproductive age women and up to 50% of women presenting with infertility. Endometriosis is defined as the presence of glands and stromal tissue of the endometrium found in locations other than the uterine cavity. Furthermore, endometrial tissue found in the ovary is called an endometrioma and that found in the myometrium is termed adenomyosis. Women with endometriosis may present with pelvic pain, dysmenorrhea, infertility, menorrhagia or bleeding per rectum/urethra.

Evidence linking endometriosis to infertility is strong but not conclusive. Distorted pelvic anatomy, altered peritoneal function, altered hormonal and cell-mediated function, endocrine and ovulatory abnormalities as well as impaired implantation have been proposed but not proven as potential mechanisms by which endometriosis

may affect fertility. Decreased fecundity has been shown in some but not all studies and improvement in fecundity with treatment of endometriosis has not been universal in all studies (149). Treatment generally consists of anti-estrogenic agents.

The most widely accepted theory for pathogenesis of endometriosis is retrograde menstruation. Although up to 90% of women are estimated to have retrograde menstruation, a combination of eutopic endometrial load, inherent invasive nature of endometrial cells, inflammatory capacity of the peritoneum and deficiencies in the immune system is thought to result in the relatively lower incidence of the condition in the general population. A single endometriotic lesion originates from a single progenitor cell (150).

Evidence of genetic contribution to the development of endometriosis is conflicting (151). Using a candidate gene approach, at least 76 genes have been implicated. However, replication of these studies for confirmation of the association has more often than not failed to confirm association. Linkage analysis studies have implicated regions in chromosomes 7 and 10 but convincing evidence for genes from these regions being causative for endometriosis is lacking (151).

Recently, a genome-wide association study of ~3200 individuals with surgically proven endometriosis and ~7000 controls from Australia and the United Kingdom was performed. The strongest association signal was on 7p15.2 (rs12700667) for all endometriosis, which was again found in a replication study from a cohort in the USA. The genome-wide significant *P* value was  $1.4 \times 10^{-9}$  (OR=1.20, 95% CI 1.13–1.27) for all endometriosis in the combined datasets. This marker on 7p is located nearby to candidate genes *NFE2L3* and *HOXA10*. In addition, epigenetic alterations in *HOXA10*, *NR5A1*, *CYP19A1*, *PGR*, *ESR2*, and *CDH1* genes have been implicated in the development of endometriosis (152).

### 32.7.16 HOXA13

Heterozygous *HOXA13* homeobox gene mutations have been identified in women with the hand–foot–uterus syndrome (153). These females may not have infertility despite developmental abnormalities of the urogenital system. The phenotypic findings in individuals with this autosomal dominant disorder typically include small hands and feet along with a duplicated uterus. The uterine anomalies consist of either bicornuate or didelphic abnormalities—defects of midline Müllerian fusion. Associated urinary anomalies, such as displaced urethral or ureteral openings may also be present in females (males may have hypospadias) (153). Hand developmental anomalies include delayed ossification or fusion of wrist bones, short middle phalanges of the fifth fingers, short first metacarpals, and small distal phalanges of the thumbs. The great toe may demonstrate a short first metatarsal and a small pointed distal phalanx. Only

a small number of *HOXA13* mutations have been characterized (154).

### 32.7.17 Obstructive Disorders of the Genital Tract

The molecular basis is only known for several disorders of the genital tract. The two most common are CAIS and Müllerian aplasia (MA).

**32.7.17.1 AR Mutations in Complete Androgen Insensitivity Syndrome.** Testosterone synthesized in the steroid enzyme pathway interacts with its receptor (Figure 32-3). The androgen receptor (AR) belongs to the steroid superfamily of nuclear hormone receptors, and is encoded by the *AR* gene. The protein consists of an amino-terminus, a DNA-binding domain, and a carboxy terminal androgen-binding domain (155). 46,XY males with CAIS who have *AR* mutations present as phenotypic females with normal breast development, minimal or no axillary and pubic hair, and a blind vaginal pouch. The phenotype results from aberrant interaction of normal androgen levels with the receptor at the target. Since testes are normal, AMH is produced, which inhibits the formation of the uterus and upper vagina. The vagina is absent or appears as a blind vaginal pouch without a cervix. The testes, which may be intra-abdominal or inguinal, are capable of making testosterone, and normal adult male levels are produced. Incomplete forms of AIS cause sexual ambiguity in males.

More than 300 different mutations, most commonly missense mutations, in *AR* have been reported to cause AIS (156,157). Interestingly, nearly all of the exon 1 mutations cause CAIS or incomplete AIS, and most of these produce a premature stop codon. However, most *AR* mutations occur in exons 2–8, despite the fact that exon 1 encodes for more than half of the protein (156).

**32.7.17.2 *WNT4* and *HNF1B* in Müllerian Aplasia.** Mayer–Rokitansky–Kuster–Hauser syndrome (MRKH), also known as MA, is a severe reproductive developmental disorder that results in the CAUV. It affects approximately 1/5000 females and is the second most common cause (10%) of primary amenorrhea in girls (158). During embryologic development, both Müllerian ducts migrate into proper anatomic position and come into contact with the urogenital sinus, which gives rise to the midline uterus as well as both fallopian tubes and the upper vagina. Renal development is intimately related to Müllerian development. Therefore, disruption of either system can affect the development of the other.

Patients with MRKH are 46,XX females that undergo normal puberty since they have normal ovarian function. They demonstrate normal adult breast development and pubic hair (which distinguishes MRKH from CAIS), but have either an absent vagina or a small blind vaginal pouch (a urogenital sinus derivative). Typically, the uterus is either absent or very hypoplastic although

fallopian tubes may be present, suggesting that the development of the caudal portions of the Müllerian ducts are more adversely affected. Rarely, the endometrium may be functional, enough to cause pelvic pain due to menstruation and genital tract obstruction. Pregnancy is only possible in these patients if oocytes are retrieved for in vitro fertilization with embryo transfer into a surrogate.

If only MA is present, which occurs in about two-thirds of patients, it is classified as type I (158). Approximately one-third of the patients with MRKH may have unilateral renal agenesis, and another 10–15% may have skeletal abnormalities, including the Klippel–Feil sequence (fusion of cervical vertebrae). This form has been classified as type II or under the acronym MURCS (Müllerian duct aplasia, unilateral renal agenesis, and cervical somite anomalies), which may also include deafness (158). Cardiac anomalies have also been reported in 10–12% of all cases (type III). In fact, MRKH has been associated with other syndromes including Holt–Oram syndrome (autosomal dominant due to *TBX5* mutations) and thrombocytopenia-absent radius (TAR) syndrome (autosomal recessive), both of which consist of associated cardiac and skeletal abnormalities. It has been suggested that perhaps CAUV, Holt–Oram syndrome, TAR syndrome, and Klippel–Feil could have a common pathway of defective T-box transcription (159).

The molecular basis of Müllerian development is largely unknown as it is difficult to identify families as pregnancy and vertical transmission will not occur (unless transmitted by a surrogate). Although a number of genes have been implicated and studied (*CFTR*, *GALT*, *HOXA7*, *HOXA13*, *PBX1*, *HOXA10*, *AMH*, *AMHR*, *RARG*, *RXRA*), only mutations in *WNT4* appear to be causative in humans (160). These patients also have mild excess androgen production resulting in hirsutism. It is also interesting that some patients with maturity onset diabetes of the young (*MODY5*) due to *HNF1B* mutations have MA (161). Several chromosomal translocations and genomic imbalances have been reported, which could be useful in uncovering the molecular basis.

## 32.8 Summary and Conclusions

Disruption of the reproductive axis may result in human disease at the level of the hypothalamus, pituitary, gonad, or outflow tracts. Many of the mutations in genes affect fertility in females. Additional genes will continue to be identified, and this will no doubt be enhanced by next generation DNA sequencing and probably by genome wide association studies. The identification of new genes in humans continues to improve our understanding of the pathophysiology of reproductive dysfunction, which will assist in genetic counseling and ultimately in treatment.

### Biographies

**Dr Lawrence C Layman** is the Robert B. Greenblatt, M.D., Chair in Endocrinology and a professor and Chief of the Section of Reproductive Endocrinology, Infertility, & Genetics in the Department of Obstetrics & Gynecology at Georgia Health Sciences University, a position he has held since 1999. He is also a faculty member of the School of Graduate Studies, the Institute of Molecular Medicine & Genetics, The Medical College of Georgia, and the Neuroscience Program. He is board certified in four specialties—Obstetrics & Gynecology; Reproductive Endocrinology & Infertility; Clinical Genetics; and Clinical Molecular Genetics.

**Dr Layman** went to medical school at the University of Cincinnati and completed a residency in Obstetrics & Gynecology at the University of Louisville followed by a fellowship in Reproductive Endocrinology and Genetics at the Medical College of Georgia. He is a physician–scientist who has been a principle investigator on four NIH grants, including continuous funding from 1997–2015 for the “Genetics of Delayed Puberty.” He was among the first to identify and characterize mutations in the *FSHB*, *GNRHR*, *CHD7*, *NELF*, and *WDR11* genes in human hypogonadotropic hypogonadism. He has nearly 100 publications and 16 book chapters.

**Dr Layman** is currently serving as a member of the Editorial Board for the *Journal of Clinical Endocrinology & Metabolism*, and is an ad-hoc reviewer for more than 20 genetics and reproductive medicine journals. He has participated as a member of multiple NIH study sections, including chairing the Reproductive Medicine Network Study Section in 1999 and 2007. He has served on national committees of the American Society of Reproductive Medicine, American College of Obstetrics & Gynecology, and the American College of Human Genetics. He has won awards in the areas of clinical medicine, research, and education including Best Doctors in America, as well as GHSU awards including: the Distinguished Faculty Award for Clinical Science Research (2002 and 2007), the APGO Award for Excellence in Undergraduate Teaching in Obstetrics & Gynecology (2010), and the 2009–2010 Exemplary Teaching Award for Medical Student Education. He was recently named the Robert B Greenblatt, MD Endowed Chair in Endocrinology. He is a member of the MD/PhD Admissions Committee and Co-Chairs the GHSU Institutional Grants Program. He mentors graduate students, medical students, residents, and faculty and has served as the PhD advisor for three graduate or MD/PhD students.

**Bala Bhagavath** completed his medical education at Madras Medical College in India. He then completed his training in Obstetrics and Gynecology in the United Kingdom and is a fellow of the Royal College of Obstetricians and Gynaecologists. He spent four years as a registrar in obstetrics and gynecology at the National University Hospital in Singapore before moving to the United States to complete a residency in Obstetrics and Gynecology at the Medical College of Georgia and a fellowship in Reproductive Endocrinology and Infertility at the UT Southwestern Medical Center. He is board certified in the USA in Obstetrics and Gynecology and subspecialty certified in Reproductive Endocrinology and Infertility. He developed an interest in the genetics of female infertility early in his career and has published many peer reviewed articles. He is currently a Clinical Assistant Professor in Obstetrics and Gynecology at Warren Alpert School of Medicine at Brown University, Providence, RI. He has just relocated to his new position as Associate Professor of Obstetrics and Gynecology, Director, Fellowship in Minimally Invasive Gynecologic Surgery, University of Rochester.

### 33.1 MALE INFERTILITY— INTRODUCTION

About one out of seven couples suffer from reproductive health disorders in the form of infertility. Male factor is an important, sometimes the only, contributory cause in about half of these involuntary childless couples. Therefore, it can be assumed that approximately 7% of all men are confronted with fertility problems. The etiology of impaired sperm production and function can be ascribed to different factors including genetic anomalies (1). With advances in diagnostic techniques, many of the men previously called “idiopathic” are now reclassified into one of the genetic disorders of male infertility. With the introduction and dissemination throughout the world of assisted reproductive techniques (ART) for the treatment of spermatogenesis defect in the male partner, many previous infertile or subfertile men can now father biological children. While males with impaired sperm production due to a genetic factor may now benefit from the wide availability and utilization of ART, the potential risk of transmitting genetic defects to the offspring deserves thoughtful consideration. At the beginning of the 1990s, the introduction of intracytoplasmic sperm injection (ICSI) gave rise to new possibilities for the treatment of severe male factor infertility, including azoospermia (no spermatozoa in the ejaculate) (2). In contrast to conventional *in vitro* fertilization (IVF), ICSI performed using sperm of poor quality is associated with considerably better fertilization rates as this technique involves the injection of a single spermatozoon directly into the oocyte (Figure 33-1). ICSI can also be applied in azoospermic patients by using either epididymal (obstructive cases) or testicular spermatozoa (obstructive or non-obstructive azoospermia). Concerns have been raised about ICSI itself because of the invasiveness of this procedure and the possibilities of adverse effects on the offspring; a number of

follow-up studies on children born after ART (including ICSI) have addressed these topics. Studies comparing children born from ICSI to those born after the less-invasive IVF failed to find a significant difference between the two techniques in terms of incidence of both malformations and genetic aberrations. In contrast, the comparison between ICSI babies and naturally conceived children provide evidence of a higher *de novo* aneuploidy rate (three-fold increase), mostly sex chromosomal aneuploidies (3). The question whether the congenital malformation rate is higher in ART babies remains debatable. In fact, some authors do not report any significant difference, whereas others assess that the risk of a major birth defect is twice as high in children born after ART (3,4). ART pregnancies are associated with low- and very-low-birth-weight babies, even in singleton pregnancies, compared to naturally conceived babies (5). Small gestational weight babies are associated with childhood and adult diseases, such as obesity, and metabolic disturbances with increased coronary heart disease risk (6–8). A correlation between semen parameters and a higher incidence of chromosomal anomalies in ICSI-derived fetuses has also been reported (9) indicating that the morbidity associated with ART does not depend on the technique used but on the underlying health risks of being subfertile, that is, more likely a carrier of constitutive or *de novo* chromosomal anomalies in the gametes. Studies to date have only followed ART children into early teenage years; therefore, there are no data on certain illnesses manifesting only later in life (10). It is therefore essential to perform longer follow-up studies in the future, with special focus on the fertility status of boys born from severely oligo/azoospermic men carrying genetic defects in their genomic and/or gamete DNA.

With the advancement and widespread use of molecular genetic tools, a number of genetic factors can now

**FIGURE 33-1** Different steps in the ICSI procedure. (A) The injection pipette presses the tail of the spermatozoon against the bottom of the Petri dish until it stops moving. The spermatozoon is then aspirated, tail first, into the injection pipette. (B) The metaphase II oocyte is immobilized by slight negative pressure exerted on the holding pipette at 9 o'clock. The polar body is held at 6 o'clock. (C) The micropipette containing a single spermatozoon is pushed through the zona pellucida and the oolemma into the ooplasm at 3 o'clock. (D) The injection pipette is withdrawn gently, and the injected oocyte is released from the holding pipette.

be easily identified and some of them are currently part of the diagnostic work-up of selected groups of subfertile patients. These factors can be transmitted as autosomal recessive, autosomal dominant, X-linked, and Y-linked traits. This chapter aims to describe known monogenic and chromosomal causes of infertility. In some instances, the genetic defects occur in infertile but nonetheless healthy males, whereas in others, the infertility is associated with additional minor or major clinical symptoms; all these aspects are discussed in the following sections.

## 33.2 CHROMOSOME ANOMALIES

### 33.2.1 Karyotype Anomalies

After the first description of the presence of an extra X chromosome in association with azoospermia (11), many surveys have been conducted to determine the contribution of chromosomal anomalies to male infertility. One of the largest reviews dealing with chromosomal aberrations in 8000 infertile males showed a 27-fold increase (3.8% vs 0.14%) of sex chromosome anomalies and a 5-fold increase (1.3% vs 0.25%) for autosomes with a combined 13-fold higher frequency (5.1% vs 0.38%) when compared to the newborns born to couples without subfertility (12). The general conclusion from these studies is that the more severe

the testicular phenotype, the higher is the frequency of chromosomal abnormalities. Patients with <10 million spermatozoa/ml ejaculate show 10 times higher incidence (4%) of mainly autosomal structural abnormalities compared to the general population. Among severe oligozoospermic men (<5 million spermatozoa/ml), this frequency is doubled to 8%, whereas in non-obstructive azoospermic men, it reaches the highest values (15–16%) and it is mainly related to sex chromosome abnormalities.

In the group of numerical sex chromosomal aberrations (sex chromosomal aneuploidy), patients with Klinefelter syndrome (KS) (47, XXY or mosaics 46, XY/47, XXY or higher grade sex chromosomal aneuploidy, i.e. XXXY, XXXXY, etc.) are the most frequent. The clinical spectrum of the phenotype of adult KS patients is very broad with the reproductive system abnormalities including androgen deficiency and infertility. Testosterone deficiency occurs in about 50% of affected KS but elevated LH and FSH levels are almost universal. The clinical phenotype of androgen deficiency in KS ranges from clinically overt hypogonadism to normally virilized males. The classical symptoms include small firm testes with hyalinization of seminiferous tubules, azoospermia or extremely severe oligozoospermia, hypergonadotropic hypogonadism with or without gynecomastia, and eunuchoid proportions (13). These patients also have

non-reproductive problems including dyslexia, executive dysfunction, behavioral problems and predilection to other systemic diseases such as diabetes mellitus and autoimmune disorders (14,15). The large majority of subjects affected by this syndrome are azoospermic. However, testicular sperm extraction (TESE) and especially microsurgical TESE (micro-TESE) followed by ICSI with an average of 30–50% of testicular sperm recovery rate may allow KS patients to generate their own genetic children (for review, see References (13) and (16)). Moreover, occasional spermatozoa can be found in the ejaculate of some mosaic patients or of non-mosaic but younger patients (17). As germ cell loss is progressive with age, the potential importance of an early diagnosis of KS might allow preventive cryopreservation of ejaculated spermatozoa in some cases and extraction of intratesticular spermatozoa in many patients to preserve fertility. According to recent reviews, children born from KS fathers are healthy and only one 47, XXY fetus has been reported so far (13,18). Despite these encouraging data, owing to the significant increase of sex chromosomal and autosomal abnormalities in the embryos of KS patients, ICSI followed by preimplantation genetic diagnosis (PGD) should be considered as an appropriate preventive option (18,19).

Other sex chromosomal anomalies include 47, XYY or 46, XX males. The 47, XYY karyotype is observed among infertile men more frequently than in newborn males (0.26% and 0.07%, respectively). However, their spermatogenic picture can range from a severe impairment to an apparent normality. The XX-male condition denotes a disorder of sex determination and occurs in about 1:20,000 newborns. In about 80% of cases, XX-male phenotype can be explained by the translocation of the SRY gene (encoding the testis determining factor) to the X chromosome. The cause of SRY-negative XX-male phenotype remains to be elucidated. Similar to KS, the phenotypic features of this syndrome include gynecomastia, female hair pattern and small testes with azoospermia. Unlike XXY males, these men are not tall. Genital malformations such as hypospadias are rare. In SRY-negative 46, XX patients, ambiguous genitalia are a frequent finding. Structural alterations of the Y chromosome are mainly found in severe male factor infertility, and cytogenetically visible deletions of the Yq are a relatively frequent cause of azoospermia. Section 33.2.2 covers the latter issue in more detail.

Robertsonian translocations, reciprocal translocations, paracentric inversions and marker chromosomes are the most frequently found abnormalities in oligozoospermic men. According to Johannisson et al. (20), a correlation exists between the increased frequency of the XY bivalent and the Robertsonian trivalent association, present during the pachytene stage of meiosis, and the extent of germ-cell impairment. The importance of the detection of these structural chromosomal anomalies

is related to the increased risk of aneuploidy or unbalanced chromosomal complements in the fetus. In cases of Robertsonian translocations, a special risk is represented by uniparental disomies, which are generated through a mechanism called “trisomy rescue” (repairing the trisomic status) during the first division of the zygote. For chromosomes 14 (the most frequently involved chromosome) and 15, both paternal and maternal uniparental disomies are pathological and give rise to severe diseases such as Angelman or Prader–Willi syndromes, despite an apparently normal or balanced karyotype.

The causal relation between chromosomal anomalies (both numerical and structural) and impaired sperm production has been suggested to be a structural effect related to alterations in the process of chromosome synapsis during meiosis. In mice, asynapsed regions may trigger the meiotic checkpoint machinery to eliminate spermatocytes (21). A similar mechanism might explain why some chromosomal abnormalities in humans are associated with deficient spermatogenesis. Another mechanism might be related to the multitude of genes involved in spermatogenesis, some of which may be dosage-sensitive and potential mutational targets for chromosomal breakpoints.

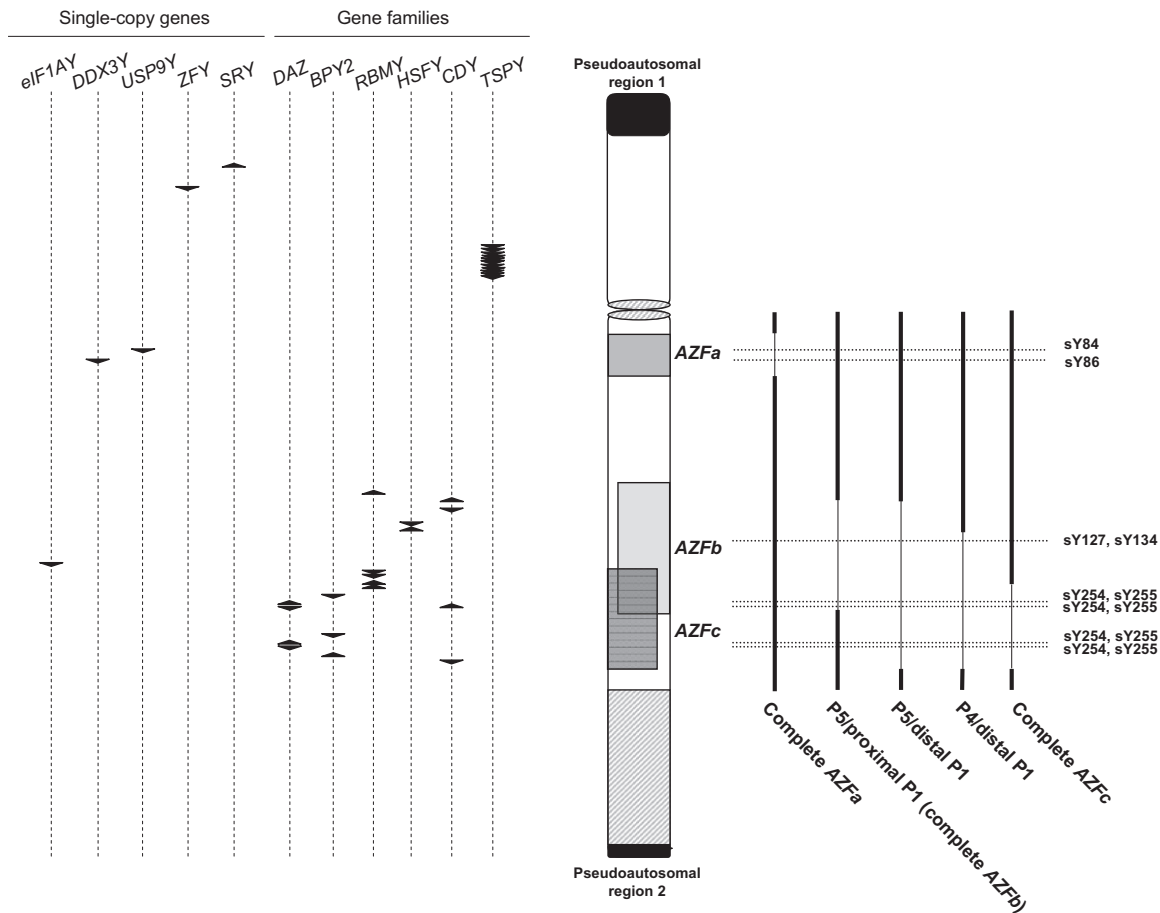

In conclusion, on the basis of the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis should be strongly considered in the diagnostic workup in all oligozoospermic men with <10 million spermatozoa/ml and in all non-obstructive azoospermic men. In case there is a family history of recurrent abortions, malformations, or mental retardation, karyotype analysis should be requested regardless of the sperm concentration. The diagnosis of a karyotype anomaly has multiple implications with both diagnostic and predictive value for the health consequences of the future offspring.

### 33.2.2 Microdeletions of the Y Chromosome

The pivotal role of the Y chromosome in spermatogenesis is supported by the presence of Y-linked genes specifically expressed in germ cells and by pathological phenotypes deriving from the deletion of regions containing the abovementioned genes.

The Y chromosome is an acrocentric chromosome and consequently contains a short arm (Yp) and long arm (Yq), demarcated by a centromeric region essential for chromosome segregation (Figure 33-2). The human Y chromosome is classically divided into two functionally distinct regions: (i) the pseudoautosomal regions (PAR1 and PAR2), which are homologous with X chromosome sequences and are responsible for correct pairing between the two sex chromosomes during male meiosis; (ii) the male specific region Y (MSY).

This chromosome is singular for its haploid nature, which precludes recombination with the X chromosome for most of its length, resulting in the accumulation of

**FIGURE 33-2** Schematic representation of the Y chromosome showing the localization of the three AZF regions as well as the two pseudoautosomal regions (PAR1 and PAR2). The Y chromosome is enriched with a number of both single-copy genes and multicopy gene families, which are indicated on the left side of the figure. On the right side, a model of the five recurrent deletions occurring on the Y chromosome is displayed. The dotted lines indicate the position of the STS primers used as region-specific deletion markers for the routine diagnostic testing.

a high proportion of segmental duplications that are arranged in direct or inverted repeats that may include palindromes (22). The presence of duplicated sequences within the chromosome allows two mechanisms to occur: gene conversion and nonallelic homologous recombination (NAHR). The first is a unidirectional conversion-based system of gene copy “correction” which permits the preservation of a certain number of Y genes from the gradual accumulation of deleterious mutations ensuring their continuity in time; on the other hand, NAHR produces recurrent deletions/duplications affecting the dosage of different Y genes.

The first description of *de novo* deletions on the Yq is in 1976 (23). In six azoospermic males, deletions were found in part of the nonfluorescent (euchromatic) region at band q11 but such deletions were not present in the fertile fathers and brothers of the patients. On the basis of this finding, Tiepolo and Zuffardi predicted the presence of an azoospermia factor (AZF) in the distal region of the Y chromosome. With the development of molecular genetics tools, it became possible to circumscribe the AZF region, in which microdeletions arise, and to highlight a certain deletion pattern with three recurrently deleted subregions in proximal, middle and distal Yq11,

designated AZFa, AZFb and AZFc, respectively (24). AZF deletions are likely to occur in germ cells during meiosis when NAHR between sister chromatids may take place. From the molecular characterization of the AZF regions, in each region, several putative Y-linked spermatogenesis genes and gene families are present.

**33.2.2.1 The AZF Deletions.** The AZFa region is 792 kb long and contains two single-copy genes *USP9Y* and *DDX3Y* (formerly *DBY*), which are ubiquitously expressed. Complete AZFa deletions occur after homologous recombination between identical sequence blocks within the retroviral sequences in the same orientation *HERVYq1* and *HERVYq2* (25). Such deletions are associated with sertoli cells only syndrome (SCOS), characterized by the total absence of germ cells in the testis.

Complete deletions of the AZFb region are caused by homologous recombination between the palindromes P5/proximal P1, which removes also part of the AZFc region belonging to P1 (26). This deletion removes 6.2 Mb (including 32 copies of genes and transcription units). The associated phenotype is azoospermia with spermatogenic arrest, resulting in the absence of mature germ cells in the testis. The AZFc region includes 12 genes

and transcription units, each present in a variable number of copies making a total of 32 copies. The complete deletion of AZFc region originates from the homologous recombination between amplicons b2 and b4 in palindromes P3 and P1, respectively (27). Contrasted with complete AZFa and AZFb deletions, a direct genotype/phenotype correlation is lacking for complete AZFc deletions, which are associated with a semen phenotype varying from oligozoospermia to azoospermia and with different testis histology. This variable phenotype might be due to a progressive regression of the germinal epithelium over time leading from oligozoospermia to azoospermia, or could also be influenced by other factors, such as the genetic background (i.e. compensation for the absence of Yq genes, by autosomal or X-linked factors), the presence of 45X lines (a more severe phenotype) and environmental factors in different individuals (28). Deletions of both AZFb and AZFc together can occur in two breakpoints between P4/distal P1 (7.0 Mb, 38 gene copies removed) or between P5/distal P1 (7.7 Mb and 42 gene copies removed). Complete AZF deletions are generally *de novo* mutations although exceptional cases of transmission have been reported and pertain uniquely to complete AZFc deletion. As described above, AZF deletions are specific for spermatogenic failure as no deletions have been reported in the genomic DNA (derived from lymphocytes) of normozoospermic men (29). Indications for complete AZF deletion screening are based on sperm count because clinical parameters such as hormone levels, testicular volume, varicocele, maldescended testis, and infections do not have any predictive value (28,29). The test is currently performed in all infertile men with <5 million spermatozoa/ml during the routine diagnostic workup. The highest deletion frequency is found in idiopathic azoospermic men (10%) who are more likely to be carrying this genetic anomaly. AZF deletions are less frequent in severe oligozoospermic men (2–5%) and have been exceptionally reported in mild oligozoospermic men. As AZF genes are mainly expressed in the testis, a number of studies have been undertaken in order to clarify if AZF deletions may cause testis-related pathologies other than spermatogenic failure. No final evidence for a cause–effect relationship was observed for varicocele, cryptorchidism and testis cancer (for review, see Reference (28)). Apart from the diagnostic value, Yq deletion screening provides additional prognostic information for testicular biopsy (TESE) in azoospermic men. In fact, deletions removing the entire AZFa or AZFb regions (“complete” deletions) represent a negative predictive factor for TESE as mature spermatozoa are unlikely to be found in the carrier testis. In case the deletion is found in a man undergoing ICSI or TESE/ICSI, genetic counseling is mandatory in order to provide information about the obligatory transmission of the AZF deletions, and therefore, the risk of giving birth to a son with impaired spermatogenesis. The diagnostic testing of Yq deletions should follow the procedure described in the European Academy of Andrology/European Molecular genetics

Quality Network guidelines (30), which is based on PCR amplification of AZF specific STS primers and control markers.

**33.2.2.2 Partial AZFc Deletions/Duplications.** In the past few years, new types of rearrangement, namely partial AZFc deletions and duplications, have been described in association with spermatogenic impairment (31). The AZFc region is organized in several amplicons containing multicopy testis-specific genes and, owing to this structure full of homologous sequences, it is particularly susceptible to NAHR events that lead to the formation of both partial deletions and duplications. Although a number of different partial AZFc deletions have been described, only one of them has been shown to be clinically relevant. This is the gr/gr deletion (named after the “green” and “red” probes used when it was detected for the first time) that results in the removal of half of the AZFc region gene content (31). This type of deletion is a significant risk factor in some populations but apparently not in others. In fact, the frequency and phenotypic expression may vary in different ethnic groups, depending on the Y chromosome background (in specific Y haplogroups, such as D2b and Q3, common in Japan and certain parts of China, the deletion is fixed and apparently does not have any negative effect on spermatogenesis). Despite controversies, it is undeniable that the gr/gr deletion has a significant effect on spermatogenesis; indeed, normozoospermic carriers have a lower sperm count compared to men with an intact Y chromosome (32). According to the largest study population published to date in Caucasians, gr/gr deletion is significantly more frequent among oligozoospermic men (3.4%) compared to normozoospermic men (0.4%) and gr/gr deletion carriers are at a 7.9-fold increased risk for spermatogenic impairment (OR=7.9, 95% CI 1.8–33.8) (33). These data, together with recent meta-analyses (32,34,35), indicate that the gr/gr deletion is a unique example of an important risk factor for impaired sperm production in Caucasian populations. Consequently, there are mainly two reasons for gr/gr deletion testing in infertile men. The deletion contributes to the etiopathogenesis of impaired sperm production as it is able to influence the spermatogenic potential of the carrier. The couple should be aware that the deletion (i.e. a genetic risk factor for impaired sperm production) will be obligatorily transmitted to their male offspring and the deletion may become complete AZFc deletion (i.e. a clear cut causative factor for spermatogenic impairment) in the next generation.

**33.2.2.3 Y Chromosome Gene-Specific Deletions.** Owing to the extent of the deletions, several genes or (part of the copies of) gene families are absent simultaneously. This makes it difficult to estimate the importance of these genes, and their proteins, in the process of normal fertility and infertility because of absence, reduction in copy number, or loss of function. The only gene-specific mutation reported to date was found in the AZFa region that contains two widely expressed genes,

*USP9Y* and *DDX3Y* (36). Both *USP9Y* and *DDX3Y* (former *DBY*) are ubiquitously expressed and have functional homologs on the X chromosome. In the first place, after sequencing both genes, the loss of *USP9Y* was believed to have a direct effect on spermatogenesis, causing azoospermia, whereas no mutation was found in the *DDX3Y* gene (37). However, azoospermia was just one of the possible phenotypes related to *USP9Y* deletion and it is also associated to mild oligo- or normozoospermia. Therefore, *USP9Y* has been proposed as a fine spermatogenic modulator, the absence of which is compatible with a highly variable phenotype probably linked to the genetic or other background of the carrier (38). Given the extreme rarity of AZF gene-specific deletions and the heterogeneous phenotype of the *USP9Y* deletion, the routine screening for AZF gene-specific deletions is not advised.

### 33.3 GENE DEFECTS INVOLVED IN ENDOCRINE FORMS OF INFERTILITY

#### 33.3.1 Mutations and Polymorphisms Affecting the Androgen Receptor

**33.3.1.1 Mutations of the AR Gene.** The androgen receptor (AR) gene is located in the long arm of the X chromosome (Xq11–12). The AR gene has four major domains: the transactivation domain; the DNA binding domain; the hinge region; and the hormone binding domain. The transactivation region of AR encloses two segments of glutamine (CAG) and glycine (GCN) repeats. The repeat segments are polymorphic (see later). Mutations of the AR gene are uncommon and occur in 1/20,000 to 1/64,000 males; about 300 mutations have been observed. Mutations of the AR gene result in a variable phenotype from a phenotypic female in the complete androgen insensitivity syndrome to an under-androgenized male with ambiguous genitalia in the partial androgen insensitivity syndrome. In addition, subtle mutations of AR can be associated with a normal male phenotype with defective spermatogenesis. Mutations in AR associated with impaired spermatogenesis and male infertility can occur in the transactivation domain or ligand-binding domain of AR (39–42). Androgens are essential for the post-meiotic development of male germ cells, differentiation of spermatids to spermatozoa and release of sperm from the germinal epithelium. Complete and selective knockout AR mouse models help to delineate the specific actions of AR in the development of the male phenotype and the regulation of normal spermatogenesis (43). AR mutations causing severe oligo- and azoospermia were first reported by Aimen et al. (44) whose study found three phenotypically normal infertile men having high production rates of testosterone with normal or elevating serum luteinizing hormone (LH) levels. AR binding in the genital fibroblasts was about half or less compared to normal men or women. The low amount of

AR with high testosterone and high-serum LH suggests that the defective spermatogenesis in these infertile men was the consequence of androgen insensitivity due to AR mutations (45). However, not all mutations of AR result in reduced androgen action and male infertility. In addition, mutations of AR at residues 727 and 866 in the ligand-binding domain interfere with coactivator interactions and are associated with severe oligozoospermia (42). Other examples include mutations in residues 798 and 712 that are associated with severe oligozoospermia. In vitro studies suggest that the mutated AR responds normally to 5- $\alpha$  dihydrotestosterone and not to testosterone. Thus, treatment with dihydrotestosterone in some mutations of AR with milder defects of spermatogenesis may be able to stimulate mutant AR function and increase the chances of fertility (42).

**33.3.1.2 Expansion of the Polyglutamine Repeats of Exon 1 of the Androgen Receptor.** Gross expansion of the polyglutamine repeats (CAG) in exon 1 within the transactivation domain of the AR results in spinal bulbar atrophy associated with decreased virilization and oligo- or azoospermia. In vitro studies have shown that the expansion of the polyglutamine tract in the AR results in a decreased AR transactivation and androgen insensitivity. Multiple reports have shown the association of longer CAG repeats in men with “idiopathic infertility” compared with fertile men in some ethnic groups (Asians in Singapore, Caucasians in Australia, United States and France) but this association was not identified in others studies (Sweden, Germany, Netherlands, Denmark). A recent combined analysis of the published studies showed that there was a small difference in CAG repeat length between infertile and fertile men and the difference appears to be more marked in Asians than Caucasians of European descent (42). This suggests that the polymorphism of the AR CAG repeat length may only play a minor role as a cause of male infertility.

#### 33.3.2 Congenital Hypogonadotropic Hypogonadism

Patients with congenital hypogonadotropic hypogonadism (CHH) have reduced or defective secretion of gonadotropin-releasing hormone (GnRH), which manifests as pubertal delay and low levels of gonadotropins (MIM \*146110). CHH in association with decreased sense of smell (anosmia or hypo-osmia) is known as Kallmann syndrome. CHH and Kallmann syndrome both present as sporadic and inherited cases, with autosomal recessive, autosomal dominant, and X-linked modes of inheritance. The distinction between CHH and Kallmann syndrome is not always obvious because GnRH deficiency with and without anosmia often occurs in different members of the same family. Genes associated with CHH can be classified according to whether the proteins they encode are involved in the development and

**TABLE 33-1 Classification of Genes and Phenotypes Associated with Congenital Hypogonadotropic Hypogonadism**

Gene	Locus	OMIM	Product	Inheritance	Associated Phenotype
Development and Migration of GnRH Neurons					
<i>KAL1</i>	Xp22.3	308700	Anosmin-1	X-linked	Hyposmia/anosmia, unilateral renal agenesis, midline facial defects (cleft lip/palate), synkinesia, oculomotor abnormalities, short metacarpals, sensorineural hearing loss, cerebellar ataxia, gut malrotations
<i>FGFR1</i> ( <i>KAL-2</i> )	8q11.2-p11.1	136350	Fibroblast growth factor receptor-1	AD, Digenic	From anosmia to normosmia, variable severity of hypogonadism, cleft lip/palate, synkinesia, dental agenesis
<i>FGF8</i>	10q24	600483	Fibroblast growth factor 8	AD, AR, Digenic	Hyposmia/anosmia Cleft lip/palate, synkinesia
<i>PROK2</i>	3p21.1	607002	Prokineticin-2	AD/AR	Sleep disorders, obesity
<i>PROKR2</i>	20p13	244200	Prokineticin-2 receptor	AD, AR, Digenic	From anosmia to normosmia
<i>CHD7</i>	8q12.1	608892	Chromodomain-helicase-DNA-binding protein 7	AD	Part of CHARGE syndrome (coloboma, heart disease, choanal atresia, retarded growth and development and/or central nervous system anomalies, genital anomalies and/or hypogonadism, ear anomalies and/or deafness), from anosmia to normosmia
<i>NELF</i>	9q34.3	608137	Nasal embryonic LHRH factor (for neurons and axonal outgrowth)	Digenic	Hyposmia/anosmia
<i>WDR11</i>	10q26	606417	Member of the WD repeat-containing protein family	AD?	None reported
GnRH Secretion					
<i>KISS1</i> <sup>a</sup>	1q32	603286	Kisspeptin		None reported
<i>KISS1R</i>	19p13.3	604161	KISS1 receptor	AR	Normosmia
<i>LEP</i>	7q31.2	164160	Leptin	AR	Severe Obesity
<i>LEPR</i>	1p31	601007	Leptin receptor	AR	
<i>TAC3</i>	12q13-q21	162330	Neurokinin B	AD, AR	Microphallus, cryptorchidism
<i>TACR3</i>	4q25	162332	Receptor for TAC3

migration of GnRH neurons from the nasal placode to the hypothalamus, regulation of GnRH secretion, or GnRH action (see Table 33-1 for details).

Mutations in genes implicated in the development and migration of GnRH neurons cause Kallmann syndrome (KS), a condition of cHH with olfactory

abnormalities. The incidence of Kallmann syndrome has been estimated at about 1 in 10,000 males and at 5–7 times lower frequency in females. The degree of both hypogonadism and smell deficiency can vary significantly not only among unrelated patients but also within affected families, even between monozygotic twins. In

**TABLE 33-2** Genes associated with cHH

	Gene	Locus	OMIM	Product	Inheritance	Associated phenotype
Development and Migration of GnRH neurons	KAL1	Xp22.3	308700	Anosmin-1	X-linked	Hyposmia/anosmia, unilateral renal agenesis, midline facial defects (cleft lip/palate), synkinesia, oculomotor abnormalities, short metacarpals, sensorineural hearing loss, cerebellar ataxia, gut malrotations
	FGFR1 (KAL-2)	8q11.2-p11.1	136350	Fibroblast growth factor receptor-1	AD, Digenic	From anosmia to normosmia, variable severity of hypogonadism, cleft lip/palate, synkinesia, dental agenesis

\**KISS1* gene mutations have been described only in association with central precocious puberty (CPP).

some families, both typical KS phenotypes and dissociated phenotypes with either hypogonadism or anosmia occur. In addition, a variety of nonreproductive, non-olfactory anomalies can be present in KS patients (46). The type of anomalies as well as their incidence depends on the gene involved. For example, renal agenesis has been described only in association with *KAL1* mutations, while cleft lip and/or palate is more common in *KAL-2* mutation carriers. To date, seven causal genes have been identified (see Table 33-2).

Because of the over-representation of males with Kallmann syndrome, a predominant X-linked form was first suspected and the gene, designated *KAL1*, was isolated from the pseudoautosomal region (Xp22.3) (MIM \*308700) (47,48). *KAL1* encodes anosmin-1, a protein showing similarities with neural adhesion molecules and proteins involved in neuronal migration and axonal path finding; it interferes with the migration of GnRH neurons and olfactory nerves to their position in the hypothalamus (49). Although this dual function of anosmin-1 may

explain its involvement in both cHH and anosmia, only approximately 50% of X-linked families have mutations in *KAL1*. In sporadic patients with Kallmann syndrome, this frequency is even lower (5%). Subsequently, other genes responsible for variably transmittable forms of Kallmann syndrome have been identified (46). To begin with, *FGFR1* (or *KAL2*; MIM \*136350) mutations cause an autosomal dominant form of Kallmann syndrome (50). *FGFR1* encodes a tyrosine kinase receptor whose signaling pathway regulates neuronal migration, differentiation and survival, as well as cell proliferation during embryonic development. Mutations in *FGFR1* account for approximately 10% of Kallmann cases. The severity of the hypogonadism and the presence of associated phenotypes have variable expressivity including incomplete penetrance. Differently from *KAL1*, mutations in *FGFR1* were found in patients with normosmic cHH. Mutations in *FGF8*, which encodes one of the many ligands of *FGFR1*, are linked to Kallmann syndrome (51). *FGF8*-related Kallmann syndrome can be transmitted either in an autosomal dominant or in an autosomal recessive manner. Another autosomal dominant form of Kallmann syndrome is caused by mutations in the *CHD7* gene, which encodes the chromodomain-helicase-DNA-binding protein 7. These mutations predict to account for 6% of all cHH cases and are part of CHARGE syndrome, which can be present at different degrees of severity depending on the type of mutation. However, mutations in *CHD7* were also identified in patients with sporadic, normosmic cHH and Kallmann syndrome who were not diagnosed with the CHARGE syndrome. Two other genes implicated in both autosomal dominant and recessive forms of cHH are *PROKR2*, encoding a G-protein-coupled receptor (PK-R2), and *PROK2*, encoding a PK-R2 ligand, prokineticin-2 (PK-2). The prokineticin–receptor interaction primes a number of signaling cascades that are important for the development of the olfactory system as well as the initiation of GnRH neuronal progenitors. Mutations in either *PROKR2* or *PROK2* are estimated to account for 5–10% of all Kallmann syndrome cases. Lately, mutations in the *NELF* gene have been described in association with Kallman syndrome. *NELF* encodes the nasal embryonic LHRH factor, which is a guidance factor for olfactory and GnRH neurons and axonal outgrowth. Recently, one case of a de novo balanced chromosome translocation form a Kallmann syndrome patient with karyotype 46, XY, t(10;12) (q26.12; q13.11) has been described and the consequent detection of multiple independent missense variants in the *WDR11* gene in cHH patients argues strongly for a causative role for *WDR11* in this disorder. As all *WDR11* mutations were heterozygous, the cHH phenotype is likely to be transmitted in an autosomal dominant manner (52).

For each genetic form of Kallmann syndrome characterized so far, the clinical heterogeneity of the disease clearly indicates that the manifestation of different

Kallmann syndrome phenotypes is dependent not only on the gene involved but also on other factors—such as epigenetic modifications or modulator genes—that remain to be identified. Moreover, the incomplete penetrance of the disease might be partly due to a digenic or oligogenic inheritance pattern. For instance, some studies show that digenic mutations (e.g. in *FGFR1* and *NELF*) can synergize to produce a given phenotype (53).

Mutations in genes implicated in GnRH secretion at a hypothalamic level are associated with normosmic cHH (54). The most potent regulator of GnRH secretion and puberty onset is represented by Kisspeptin-1, encoded by the *KISS1* gene, which operates through interaction with the G-protein-coupled *KISS-1* receptor (also known as GPR54), encoded by *KISS1R*. While *KISS1* mutations have been described only in association with central precocious puberty (55), inactivating mutations in *KISS1R* account for about 5% of normosmic cHH cases, showing an autosomal recessive pattern of transmission. The same inheritance pattern is typical of mutations in the *LEP* gene, encoding the fat-derived hormone leptin, and the *LEPR* gene, which encodes the leptin receptor. Such gene alterations have been found in patients with severe obesity and hypogonadotropic hypogonadism and account for less than 5% of normosmic cHH. Another critical central regulator of GnRH secretion is neurokinin B (NK3R), a member of the substance P-related tachykinin family encoded by the *TAC3* gene. Loss-of-function mutations in *TAC3* or *TACR3* (encoding the neurokinin B receptor, NK3R) lead to severe congenital gonadotropin deficiency and pubertal failure (56). Only three cases of hypogonadotropic hypogonadism have been described in association with mutations in *PCSK1*, which encodes a neuroendocrine convertase (also known as prohormone convertase) that processes precursor peptides to release bioactive fragments (e.g. proinsulin). Although no reports have been published on the molecular mechanisms by which *PCSK1* mutations cause hypogonadism, the impairment of GnRH prohormone precursor processing is probably involved in these cases. The few *PCSK1* mutation carriers reported to date suffer from obesity as carriers of *LEP/LEPR* mutations. cHH can also be part of the adrenal hypoplasia congenita when the *NROB1* gene is mutated. *NROB1* encodes the orphan nuclear receptor DAX-1, which is crucial for the development and function of the adrenal gland and hypothalamic–pituitary–gonadal axis. Consequently, *NROB1* mutations are uncommon in hypogonadism without clinical evidence or a family history of adrenal failure. However, some cases of *NROB1* mutations leading only to reproductive disorders with normal adrenal function or mild/compensated adrenal failure have been described. An important feature of patients with these mutations is the resistance of azoospermia to gonadotropin stimulation. This is possibly due to the fact that *NROB1* is expressed in sertoli cells, and thus plays an important role in spermatogenesis.

An obvious candidate gene for normosmic cHH is *GNRH1*, which encodes gonadotropin-releasing hormone 1. Nevertheless, only one example of *GNRH1* mutation causing a familial HH has been reported to date (57).

Mutations in *GNRHR* are established to cause normosmic cHH. Encoding the GnRH receptor, *GNRHR* is the only gene implicated in GnRH action. Germline mutations in *GNRHR* were the first to be identified in hypogonadotropic patients and compound heterozygosity is frequently found for mutations with partial effects on *GNRHR* signaling. The Gln106Arg substitution is one of the most frequent mutations occurring in *GNRHR*. Large-scale screenings indicate that *GNRHR* mutations account for 3.5–16% of sporadic cases of normosmic cHH and up to 40% of familial cases of normosmic cases, which are transmitted in an autosomal recessive manner (54).

cHH associated with either anosmia (Kallmann syndrome) or a normal sense of smell is a treatable condition. Exogenous therapy with pulsatile GnRH or gonadotropin therapy usually restores normal pubertal development and fertility, whereas androgen therapy induces virilization. In about 80% of azoospermic men affected by cHH spermatogenesis can be induced by GnRH or gonadotropin therapy within 2 years and spontaneous pregnancy is highly likely during gonadotropin treatment. Although cHH is widely thought to require a lifelong therapy, reports on the sustained reversal of this disorder are available (58–60). These studies indicate that sustained reversal of cHH includes Kallmann syndrome patients and normosmic cHH, and this phenomenon has been described in association with mutations in a number of genes: *GNRHR*, *FGFR*, *KAL1*, *KISS1*, *TAC3* and *PROK2R*. To date, no clinical or laboratory data are available for the prediction of future reversibility; therefore, it is advised that all patients affected by cHH should be reassessed for recovery of the hypothalamo–pituitary–gonadal axis after a certain period of hormonal replacement therapy.

### 33.3.3 Persistent Müllerian Duct Syndrome

Persistent Müllerian duct syndrome (PMDS; MIM \*261550) is characterized by the persistence of the Müllerian duct derivatives (i.e. uterus, cervix, fallopian tubes and upper two-thirds of vagina) in a 46, XY patient with perfectly virilized external genitalia. PMDS leads to an uncommon (<200 cases described) autosomal recessive form of male pseudohermaphroditism with cryptorchidism (and associated azoospermia) and/or inguinal hernia as most prominent clinical features. In the absence of long-standing cryptorchidism, the testes usually contain germ cells (61).

In normal males, regression of the Müllerian duct is conducted by the action of the anti-Müllerian hormone (AMH), a member of the transforming growth factor- $\beta$

(TGF- $\beta$ ) family, and two receptors necessary for AMH ligand binding (AMH type II receptor) and signal transduction (AMH type I receptor) (62,63). Mutations leading to PMDS have been identified in the *AMH* gene (localized at chromosome 19p13.3) and in the AMH type II receptor (chromosome 12q13) (64,65). Depending on the affected gene, either normal quantities of AMH are present in the testis (AMH type II receptor mutations; MIM \*600956) or no AMH is produced (AMH gene mutations; MIM \*600957). Some of these mutations do not affect the AMH secretion rate (normal serum levels were detected), suggesting that they might only compromise the function and the bioactivity of the hormone (64). However, some PMDS patients have no mutations in either of these two genes, indicating that other genes are involved in PMDS. The AMH type I receptor would be a likely candidate, but mutations in this receptor have not yet been identified.

### 33.3.4 Luteinizing Hormone, Luteinizing Hormone Receptor and FSH and FSH Receptor

Gonadotropins—LH, follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG)—have a common  $\alpha$ -subunit and a hormone-specific  $\beta$ -subunit (66). So far, mutations in the  $\alpha$ -subunit have not been described but on the basis of a knockout mouse model, the phenotype would probably include hypogonadotropic hypogonadism, and hypothyroidism due to associated thyroid-stimulating hormone (TSH) deficiency (67).

The crucial role of LH in the maintenance of Leydig cell function is demonstrated by the description of a single patient carrying the same mutation in both alleles of the LH  $\beta$ -subunit (*LH- $\beta$* ; MIM \*152780). This patient is presented with hypogonadism (small, bilaterally descended testes) and pubertal delay (68). Immunoreactive LH was higher than normal but bioactive LH was lower, explaining the delayed puberty. A testicular biopsy revealed spermatogenic arrest and a complete absence of Leydig cells, indicating the absolute need of LH in Leydig cell formation. Molecular analysis of his *LH- $\beta$*  gene demonstrated the presence in both alleles of an arginine substitution for a glutamine (Q34R), which impaired hormone-receptor binding. As no other patients have been described, LH- $\beta$  deficiency is probably a very rare cause of autosomal recessive hypogonadism.

Both inactivating and activating mutations have been described for the LH receptor (MIM \*152790) (69–71).

Inactivating mutations lead to an impaired testosterone response to LH and hCG as both these gonadotropins bind to the LH receptor. Inactivating mutations were first reported in two siblings with 46, XY karyotype who presented with female external genitalia and primary amenorrhea (around 40 years of age) (72). Depending on the residual function of the receptor, patients (46,

XY) carrying such mutations can present with phenotypes ranging from complete failure of virilization, through hypospadias, to micropenis, absence of puberty and infertility. Several other patients of male genetic sex with inactivating mutations in the LH receptor have since been described, and the mutations impair either signal transduction or ligand binding, or both (73,74). Women carrying inactivating homozygous mutations in the LH receptor might suffer from oligomenorrhea or amenorrhea although they undergo a normal pubertal development (69).

Activating mutations in the LH receptor lead to a constitutively activated receptor without stimulation by a gonadotropin ligand (69). These mutations are associated with familial precocious male puberty, an autosomal dominant condition in which puberty in patients is initiated at the age of 1–4 years (MIM \*176410). The constitutively activated LH receptor does not induce puberty in females, probably because both LH and FSH are required for the activation of ovarian steroidogenesis.

The exact role of FSH in spermatogenesis is less clear. In human studies, FSH is necessary for quantitatively normal spermatogenesis (75). In fact, mutations of *FSHβ* (FSH  $\beta$ -subunit) and *FSHR* (FSH receptor) have been reported mainly in women (76,77). However, azoospermia has been reported in two men carrying mutations on the so-called “seatbelt” region of *FSHB*, while milder phenotypes could result from mutations in other regions of the glycoprotein (78).

### 33.4 MONOGENIC DEFECTS IN POST-TESTICULAR AND PRIMARY TESTICULAR FORMS OF MALE INFERTILITY

#### 33.4.1 Post-testicular Form: Congenital Absence of the Vas Deferens

Congenital bilateral absence of the vas deferens (CBAVD; MIM \*277180) is a post-testicular disease characterized by the absence of the scrotal vasa, which results in a blockade of the transport of the spermatozoa from the testis or the epididymis to the distal genital tract. This form of obstructive azoospermia is responsible for 1–2% of male infertility and for up to 6% of all patients with obstructive azoospermia (79). The congenital unilateral absence of the vas deferens (CUAVD) is associated with oligozoospermia. CBAVD is also present in most males with cystic fibrosis (CF; MIM \*219700), the most common autosomal recessive disease in populations of Caucasian origin. The similarity between infertility in CF males and in males with CBAVD without other clinical characteristics of CF led to the hypothesis that isolated CBAVD is an incomplete form of CF (80). CF occurs with a frequency of about 1 in 2500 live births (carrier frequency 1 in 25) and is caused by mutations in *CFTR*, which encodes the

CF transmembrane conductance regulator, a protein involved in chloride conduction across epithelial cell membranes (81–83). The most widely diffused mutation in *CFTR* is delta F508 ( $\Delta F508$ ), which accounts for about 70% of the total CF mutations in Caucasians. This 3-bp deletion in exon 10 leads to the deletion of a phenylalanine at amino acid position 508 of the protein (p.Phe508del) and is responsible for the majority of defects found in CF and in congenital absence of the vas deferens (CAVD) patients. *CFTR* is one of the most studied genes in the human genome: more than 1400 mutations have been identified in *CFTR* and most of these occur with a low frequency or are even unique to single CF families. A wide variation in phenotype occurs with *CFTR* mutations. Patients with the gravest form of CF have mutations in both alleles of *CFTR* resulting in no residual *CFTR* activity. Patients with milder clinical manifestations such as CAVD, instead, might present with two scenarios: a severe mutation in one allele and a mild mutation, which leaves some residual *CFTR* activity, in the other allele; or, two mutant alleles with mild effect on the protein.

In the majority of males with CBAVD (about 80%), *CFTR* mutations can be found (84). Many of these mutations are unique to CBAVD and are not found in CF patients. Moreover, a role of intron 8 variants (IVS8-5 T, IVS8-7 T, and IVS8-9 T) in the phenotypic expression of mutations has also been established. The three variants include different numbers of thymidine within the acceptor splice site of intron 8, i.e. 5, 7 and 9 thymidines, respectively. The length of the thymidine (T) tract affects the splicing efficiency of exon 9 and thus the percentage of normal *CFTR* mRNA. The 5 T tract is the least efficient and allows about 8–10% of *CFTR* mRNA to be completed with exon 9. The splicing efficiency of the 5 T variant, probably influenced by other polymorphisms in *CFTR* (84,85), is variable between different individuals and different tissues of the same individual, but in the epididymal epithelium and the vas deferens, it is consistently lower than in other tissues (84,86). The 5 T variant of *CFTR* appears to occur at a much higher frequency in CBAVD than in the general population (21% vs 5%) (87). For all these reasons, the 5 T variant has been classified as a mutation associated with CBAVD but with incomplete penetrance. In about 20% of patients, CBAVD does not seem to represent a mild form of CF (88,89). These patients have CBAVD-associated urinary tract malformations, and no *CFTR* mutations are found in this situation. The etiology of this form of CBAVD remains unknown but is probably caused by damage to the Wolffian duct before its split into the reproductive and the ureteral part at about 7 weeks gestation. Evidence is provided by the fact that neither CF nor CF-associated CBAVD patients present alterations in the ureteral ducts. In fact, *CFTR* dysfunction probably leads to damage of the genital ducts, either through a morphogenetic defect

or through a progressive obstruction due to excessive mucus secretion, once the split of the Wolffian duct has occurred (90).

The condition CUAVD is also associated with mutations in *CFTR* when contralateral genitourinary anomalies are present (91). This is not the case when anatomically complete and patent vasa are present on the side of the palpable vas. These patients often present with renal abnormalities at the ipsilateral side of the absent vas.

Involvement *CFTR* in other conditions of male infertility has also been suggested (92–94). An increased frequency of *CFTR* mutations was described in patients with obstructive azoospermia (non-CBAVD) and reduced sperm quality and quantity; these data have not been confirmed by subsequent studies and currently, the *CFTR* mutation screening should be limited to obstructive defects, which can be correlated to the reduction of functional *CFTR* protein (i.e. CAVD on at least one side) and idiopathic epididymal obstruction. Given that the frequency of a particular *CFTR* mutation is variable among different geographic areas and shows important ethnic differences, the routine mutation screening is based on a panel of mutations (normally 30–80), which are the most common for a given population. Since the 5 T tract variant is now considered a mild *CFTR* mutation rather than a polymorphism, it should be analyzed in each CAVD patient. If no mutations are found, a full-sequence analysis is performed.

Patients affected by CAVD may have sperm in their ejaculate (unilateral forms, CUAVD) or are azoospermic (bilateral forms, CBAVD). By combining the application of testis biopsy with ICSI, both CF and CBAVD patients may now generate their own biological children although the risk of transmitting their *CFTR* mutations to their descendents has to be considered. As the carrier frequency of *CFTR* mutations in people with Northern European descent is high (1:25), the screening for CF gene mutations in the female partners of men with CAVD without congenital kidney anomalies or with CF should be recommended before assisted reproduction. If mutations are detected in both partners (possibly by sequencing *CFTR*), the risk of an offspring with CF or mild forms of CF is very high and PGD should be offered to the couple. However, in many cases, it remains difficult to make precise risk estimates due to different degrees of penetrance of the same genotype between different individuals.

Given its association with obstructive azoospermia in combination with chronic sinopulmonary disease, a condition referred to as Young syndrome (MIM \*279000) was thought to be related to CF. However, no increased frequency of *CFTR* mutations is found in these patients, indicating that Young syndrome is a CF-independent disorder. Instead, it might be related to childhood mercury poisoning and thus be an acquired disease (95).

### 33.4.2 Monogenic Defects in Primary Testicular Failure

On the basis of data obtained from animal models, expression studies, linkage analyses and cytogenetic findings, a number of candidate spermatogenesis genes have been identified and represent the most obvious targets for mutation screening in men with spermatogenic failure (96). These genes can be classified according to whether they are involved in the endocrine regulation of spermatogenesis (discussed in detail in Section 33.3), common cell functions, and specific spermatogenic functions.

Studies on genes involved in common cell functions that are relevant also for normal spermatogenesis are relatively few and are mainly single studies. An exception to this statement is *MTHFR*, which encodes methylenetetrahydrofolate reductase, one of the key enzymes of folate metabolism, which reduces 5,10-methylenetetrahydrofolate to its biologically active form 5-methyltetrahydrofolate. In particular, the C677 T polymorphism of *MTHFR* correlates with decreased *MTHFR* activity. Altered folic acid metabolism influences DNA methylation, and subjects with homozygous C677 T mutations have a lower level of genomic DNA methylation compared to wild-type controls (97). As aberrant DNA and protein methylation are likely to affect spermatogenesis, C677 T has been extensively analyzed in infertile patients from different populations (98–102) with highly discordant results. The most likely explanation is that the polymorphism is relevant only in specific environmental conditions in combination with low dietary intake of folates (34).

Regarding those genes involved in specific spermatogenic functions, not only Y-linked genes but also an increasing number of autosomal and X-linked candidate genes are described to play a role in the complex process of spermatogenesis (103). In particular, the X chromosome appears to be of special interest as men are hemizygous and de novo mutations will have an immediate impact because compensation by a second normal allele is not possible. Furthermore, this chromosome contains an unexpectedly high number of X-linked genes expressed in the testis that might have an important role in spermatogenesis (104). However, human data are extremely scarce in this regard and only seven selected X-linked genes have been screened in infertile men (*AR*, *SOX3*, *USP26*, *NXF2*, *TAF7L*, *FATE* and *AKAP4*). Except for *AR*, no infertility causing mutations have been described thus far (105).

A large number of genetic variants, mainly in autosomes, have been proposed as risk factors for male infertility, but in many cases, only sporadic data are available and when more studies are published on the same polymorphism, results are often contradictory (34,103). The only clinically relevant polymorphism confirmed by meta-analyses is the gr/gr deletion, about which more

detail is given in Sections 33.1 and 33.2.2. Whether the paucity of results is due to a real rarity of causative gene mutations/genetic risk factors or to an inappropriateness of the currently used approaches is yet to be established.

## 33.5 SYNDROMIC MONOGENIC DEFECTS

### 33.5.1 Bardet–Biedl Syndrome

Bardet–Biedl syndrome (BBS; MIM \*209900) is characterized by obesity, polydactyly, mental retardation, renal anomalies, retinal pigmentary dystrophy, and hypogenitalism (106,107). Additional characteristics include deafness, diabetes mellitus, dental anomalies, and small stature. In females, vaginal atresia and delayed puberty are observed. In males, hypogenitalism includes cryptorchidism, micropenis, and various degrees of hypospadias.

BBS is primarily inherited as an autosomal recessive disease but more complex forms of inheritance might exist (108,109). The incidence is less than 1 in 100,000 live births. The syndrome seems to be associated with *BBS1* (MIM \*209901) in most of the families (36–55%). However, the condition is genetically very heterogeneous, and 14 genes have so far been implicated (110).

### 33.5.2 Prader–Willi Syndrome

Prader–Willi syndrome (PWS; MIM \*176270) is a neurobehavioral disease that affects both males and females and is characterized by infantile hypotonia, developmental delay and mental retardation, obesity, and hypogonadism (111). In males, the hypogonadism manifests as cryptorchidism and scrotal hypoplasia. The prevalence of PWS is from 1/10,000 to 1/15,000. PWS is caused by a disturbance in the parent-of-origin pattern of inheritance at chromosome region 15q11–q13 (imprinting) and results from the absence of expressed paternal genes from this imprinted region. Several genes at 15q11–q13 are expressed only from the paternal chromosome, and PWS results from paternal interstitial deletion of the region (about 70% of patients), maternal disomy (29%), or a defect in the imprinting mechanism (1%). The mechanism underlying imprinting is not well understood, but parent-of-origin-specific DNA methylation is important in the regulation of the expression of imprinted genes.

### 33.5.3 Primary Ciliary Dyskinesia

Primary ciliary dyskinesia (PCD, also known as immotile cilia syndrome; MIM \*242650) constitutes a genetically heterogeneous group of disorders resulting from the absence of mucociliary clearance of the airways and other ciliated structures because of severe or complete immotility of the cilia (112). The major clinical features are

chronic respiratory tract disease, rhinitis, and sinusitis. Most males are also infertile because of immotility or poor mobility of spermatozoa as a consequence of structural and functional abnormalities in the central part of the sperm flagella. About half of the patients with PCD also display situs inversus, a condition known as Kartagener syndrome (MIM \*244400). The prevalence of PCD is around 1/25,000 and that of Kartagener syndrome 1/50,000. The mode of inheritance is autosomal recessive in the majority of cases.

The diagnosis of PCD can be made only by electron microscopy to identify the defective components in the cilia. The common defect in PCD is the absence of dynein arms, the structures necessary for the generation of movement of cilia and sperm tails. At the molecular level, mutations in three genes have been identified as causing PCD. Two of these genes, *DNAH5* and *DNAH11*, encode axonemal heavy dyneins while the third gene, *DNAI1*, encodes an intermediate dynein. Several other genes involved in cilia formation have been identified, but no mutations have been reported (99).

### 33.5.4 Noonan Syndrome

Noonan syndrome (MIM \*163950) is an autosomal dominant disorder characterized by short stature, congestive heart failure (most often pulmonary valve stenosis or hypertrophic cardiomyopathy), and a typical facial dysmorphism with posteriorly rotated ears. About half of the male patients with Noonan syndrome have azoospermia or oligozoospermia resulting from bilateral cryptorchidism. Affected females and males with normally descended testes are fertile (113). The incidence of Noonan syndrome is estimated at 1/1000–1/5000 live births. Mutations in *PTPN11*, a gene encoding the non-receptor protein tyrosine phosphatase SHP-2, cause Noonan syndrome in approximately 50% of patients. A significant proportion of Noonan syndrome cases (almost 50%) are the result of new mutations (sporadic cases) that probably originate most of the time in the paternal germline, at least when associated with *PTPN11* mutations (114).

In some Noonan syndrome-like conditions such as cardio-facio-cutaneous, Noonan/neurofibromatosis and Costello syndromes, no mutations in *PTPN11* were found (115). In contrast, mutations in *PTPN11* are found in LEOPARD syndrome (116).

### 33.5.5 Myotonic Dystrophy

Myotonic dystrophy (DM; MIM \*160900) is an autosomal dominant disease caused by a trinucleotide (CTG) repeat expansion in *DMPK* at chromosome 19p13.3 (117–120). It is the most common form of adult muscular dystrophy (prevalence 1/7000–1/8000 births)

characterized by myotonia and muscle weakness and wasting. Additional anomalies include cardiac conduction disturbances, cataracts, and progressive testicular tubular atrophy in 60–80% of males.

The number of CTG repeats in the 3′ untranslated region of *DMPK* is polymorphic in normal individuals and ranges from 5 to 35. Genes with 50–80 repeats are unstable and the number of repeats is likely to expand on transmission to the offspring. The severity and time of onset of the disease will, in general, be related to the number of repeats. The progressive earlier appearance of the disease in successive generations with an increase of disease severity is called anticipation (121,122). In its severest form, a few thousand repeats are present. A gene for a less-frequent form of myotonic dystrophy (DM2, proximal myotonic myopathy or PROMM, MIM \*602668) is clinically very similar to classic DM and is caused by a CCTG expansion in intron 1 of *ZNF9* (123).

### 33.6 CONCLUSION

In this chapter, most of the more common genetic defects associated with male infertility are described in detail. With the advent of testing for Y chromosome microdeletions, about 7% of those patients previously designated “idiopathic” now have a defined cause. Testing for Y chromosome microdeletions is necessary before performing TESE/ICSI because deletions of the AZFa and AZFb regions of the Y chromosome will lead to absence of spermatogenesis in male offspring. With the advancement of ART including ICSI and TESE, previously infertile men can now generate their own progeny. Patients include those with KS and those with CBAVD and CF. However, with the wider use of these sophisticated but effective forms of ART, the couple has to be counseled about the potential transmission of the gene defect to the progeny. In cases where infertility may be associated with a severe medical condition, the option of PGD needs to be discussed with the couple. It should be noted that ART babies have smaller birth rates and the long-term effects of low birth weight in population-based studies are not known. Considering the high number of genes involved in spermatogenesis (more than 2000) and the fact that only a fraction of them has been analyzed so far, we expect that new genetic factors will be discovered in the near future. In the era of ICSI, the definition of genetic causes is urged, considering that still about 50% of infertile men have an unknown etiology and are likely to be carriers of unknown genetic anomalies.

Besides genetic factors, it is expected that altered epigenetic modifications of the male gamete may also play a role in male infertility. Some studies suggest that there is an increased incidence of rare imprinting disorders in babies conceived by ART, however, to date, only few studies have focused on the analysis of imprinting abnormalities in spermatozoa derived from infertile men

(for review, see Reference (124) and references therein). Recently, it has been reported that the repertoire of epigenetic modifications in the mature sperm may have a potential role in the developing embryo (125). These epigenetic changes include DNA demethylation and the retention of modified histones at important developmental, signaling and micro-RNA genes. Alterations of the sperm epigenome may therefore reduce the fertilizing potential of spermatozoa and thus become a new cause of male factor infertility. However, it is also predicted that epigenetic alterations may not necessarily abolish the sperm fertilizing ability although they would still occur with a higher frequency in infertile men. Future epigenetic studies are warranted, especially if we consider that methylation alterations in the gametes of infertile patients may pose a risk for transgenerational epigenetic inheritance.

### Biographies

**Csilla Krausz, MD, PhD.** Dr Krausz is a senior consultant in Andrology and an associate professor of Endocrinology in the Department of Physiopathology at the Medical School of the University of Florence. She is an Academician of the European Academy of Andrology (EAA). Her current research interest is focused on Y chromosome genes, rearrangements, haplogroups, genetic factors related to impaired sperm production, cryptorchidism and testis cancer. She is an expert in male fertility and has authored many publications on topics related to the genetics of male infertility.

**Chiara Chianese, MSc.** Chiara Chianese obtained her BSc in Health Biotechnologies at the University of Naples “Federico II” and her MSc in Human Reproduction at the University of Florence. She is currently a research fellow with Dr Csilla Krausz at the Department of Clinical Physiopathology, where she focuses her studies on the genetic and epigenetic of male infertility.

**Ronald Swerdloff, MD.** Dr Swerdloff is a professor of Medicine, David Geffen School of Medicine at the University of California Los Angeles and chief of the Division of Endocrinology and Metabolism at Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute. Dr Swerdloff is internationally known for his basic and translational research on male reproductive biology including the regulation of spermatogenesis, male infertility, male contraception and androgen drug development.

**Christina Wang, MD.** Dr Wang is a professor of Medicine, David Geffen School of Medicine at the University of California Los Angeles and Director of the General Clinical Research Center at Harbor-UCLA Medical Center and the Los Angeles Biomedical Research Institute. Dr Wang is an internationally known investigator in male reproductive endocrinology and biology. Her research spans from basic, translational and clinical research with a focus on androgen metabolism and replacement, male reproductive aging, male infertility, and regulation of spermatogenesis.

### 34.1 BACKGROUND

The loss of a desired pregnancy, while sad, is not an uncommon event. It is well established that 15% of recognized pregnancies are lost (1), usually during the first 13 weeks of pregnancy (2), with the incidence of early pregnancy loss increasing with maternal age and a history of prior pregnancy loss. An additional 22% of conceptions are lost between implantation and the clinical recognition of pregnancy (preclinical losses), bringing the total rate of early pregnancy loss to nearly 40% of conceptions (3). The vast majority of fetal loss (4) occurs during the first trimester of pregnancy, with the loss rate dropping dramatically after 12 weeks' gestation. The incidence of these early losses is directly correlated with the age of the mother, as the incidence of pregnancy loss increases threefold over the mean in women who are between 34 and 39 years of age, and sixfold in women over 40 years of age. As early as 1984, Hassold and Chiu (5) demonstrated that the pattern of age-related fetal loss closely mirrors the increased incidence of aneuploidy associated with advanced maternal age, suggesting a relation between these two phenomena. Yet, the obstetrical literature is replete with investigations of a variety of other causes of pregnancy loss, with little consensus on the factors responsible for the limited viability of human conceptions, and many reviews reiterating that in 50% of couples experiencing pregnancy loss, the causative factor cannot be determined. This chapter will review the data on the etiology of pregnancy loss, focusing on embryonic and fetal chromosome abnormalities and other established genetic causes that are usually associated with fetal loss early in gestation, and discuss other

factors that contribute to later pregnancy loss, as well as recurrent loss.

### 34.2 DEFINITION OF TERMS

Pregnancy loss can be defined as the unplanned, spontaneous loss of a pregnancy before the fetus is capable of extra uterine survival. In the United States, the term spontaneous abortion or miscarriage is applied to a pregnancy lost prior to 20 weeks' gestation, after which time the loss is defined as either an intrauterine fetal death or stillbirth. Preclinical abortion (before 6 menstrual weeks' gestation) occurs when the conceptus fails to implant or aborts shortly after implantation. The term missed abortion is used when the fetus has died but is retained in the uterus, often for several weeks. A pregnancy is classified as an inevitable abortion when uterine contractions cause dilation of the cervix, leading to either a complete abortion (all products of conception (POC) are expelled and the cervix subsequently closes) or an incomplete abortion (only a portion of the POC are passed through the cervix). Recurrent abortion has typically been defined as two to three or more losses. Recurrent fetal loss is less common, involving only 1–2% of couples, and recurrent fetal loss at or beyond 14 weeks of gestation is a very rare event.

The majority of spontaneous abortions occur in pregnancies with incomplete fetal development (6). However, abnormal development does not always end in spontaneous abortion, as is evident from the 3–4% population incidence of sporadic congenital anomalies in the newborn population.

### 34.3 EARLY PREGNANCY LOSS

#### 34.3.1 Cytogenetic Abnormalities in Human Conception

It has been known since the mid-1960s that chromosome abnormalities are found by cytogenetic evaluation of cultured tissue from spontaneous abortions in at least 60% of first-trimester losses. More recent data suggests that as high as 80% of first-trimester losses are the result of an unbalanced karyotype in the fetus, making chromosome anomalies the single most common reason for the loss of a pregnancy during the first trimester. An early epidemiologic study (7) on 1500 spontaneous abortion samples collected from 1966 to 1972 reported that 61.5% of pregnancy losses in which the embryo was less than 12 weeks of age demonstrated a chromosome abnormality by culturing tissue collected at the time of the loss. Historically, most laboratories culturing this type of “products of conception” material find a significant excess of 46,XX karyotypes among the samples without a chromosome error, and this excess of 46,XX normal female results has been ascribed to nonviable fetal material with the growth of maternal tissue that was present in the sample collected. In such cases, it is the maternal, rather than the fetal karyotype that is being described, and this falsely inflates the number of “normal” fetal karyotypes reported. In addition, the early studies were done in the “pre-banding era,” when the techniques available would fail to recognize more subtle genomic abnormalities (such as deletions or duplications). Other complications limiting the evaluation of the true incidence of abnormal fetal genomes by doing tissue culture and routine chromosome analysis on abortus specimens include the rate of culture failure due to nonviable specimens (either due to missed abortions or samples with nonviable genetic alterations) and contaminated samples that cannot be grown and evaluated. Hence, the value of approximately 60% aneuploid fetuses reported by this and other early studies should be considered a minimum estimate of the incidence of chromosome abnormalities in miscarriages. Thus it is not surprising that a recent study, using semidirect analysis of chorionic villi (CV) from pregnancies that arrested in the first trimester (8) found that 80% of early pregnancy losses demonstrated a chromosome abnormality. As clinical evaluation of ongoing pregnancies have shown confined placental mosaicism, which is the presence of a chromosome abnormality in extraembryonic tissue that is not present in the fetus, in only 1–2% of CV studies, this work of Morales et al. (8) suggests that upwards of 80% of early pregnancy losses actually are the result of a chromosome anomaly in the fetus.

The knowledge that 15% of recognized human pregnancies are lost and that upwards of 80% of these are aneuploid, coupled with the frequency of unbalanced chromosome abnormalities in stillborns and live borns (5% and 0.4%, respectively), suggests that chromosome

abnormalities occur fairly frequently at conception in humans. Yet the “order of magnitude” decrease in the incidence of chromosome abnormalities from the first trimester of pregnancy, to the last trimester of pregnancy, and then again to birth, suggests that there is very strong selection against human fetuses with unbalanced chromosome complements. A variety of methodologies, designed to improve preimplantation genetic diagnosis of embryos fertilized in vitro, have provided information addressing the incidence of abnormal karyotypes close to the time of conception. It is important to remember when evaluating these studies that they are complicated by the use of embryos created in vitro and the very manipulation of gametes and embryos in an artificial setting may affect genomic stability (9). In addition, besides discrepancies between the techniques themselves, the populations from which the embryos were obtained are not always equivalent, with varying ages and pregnancy histories, which as shown later, will influence the incidence of chromosome abnormalities. But these studies provide previously unrecognized information about the incidence and complexity of embryonic chromosome abnormalities, and show an unanticipated very high frequency of chromosomal abnormalities in preimplantation embryos, which may be correlated with the high incidence of early loss in both in vivo and in vitro embryos.

Fluorescence in situ hybridization (FISH) analysis of fertilized oocytes, early embryos and individual cells from such embryos obtained during the in vitro fertilization (IVF) process has provided new insights into the complexity of human reproduction. This approach uses differentially colored fluorescent probes, directed to single regions, often the centromere, of a chromosome, to assess the chromosome content of interphase cells. While this technique can be applied to single cells, or nonviable samples, it is limited by the number of chromosome-specific probes that can be evaluated in a single study and thus cannot provide a complete chromosome analysis. These studies, depending on the probe set used, have confirmed a high level of aneuploidy (30–83%) in early embryos (10–15). In addition, these studies have revealed the presence of both autosomal monosomy and nullosomy (10), which are virtually never observed in live borns or cell culture of miscarriage samples, but may contribute to the incidence of preclinical pregnancy loss. As seen in both prenatal diagnosis and newborn surveys, these studies revealed that the incidence of fetal aneuploidy is highly correlated with advancing maternal age (11), so that the incidence of aneuploid embryos observed is directly proportional to the mean maternal age in the group being studied. FISH done on multiple cells from early embryos also has shown a high rate of embryonic mosaicism, with up to 83% of 4-day embryos showing more than one cell population (12). The same study demonstrated that this mosaicism, which by definition is a postfertilization event, declines with further development of the embryo, possibly because of the death of abnormal cells, or an aneuploid rescue mechanism, so that only 42% of

8-day embryos showed multiple cell lines. An even more unexpected observation was the presence in several multi-cell FISH studies of “chaotic embryos” showing extreme mosaicism with different chromosome abnormalities in almost every cell evaluated from the same embryo (12). All the aberrations detected by FISH contribute to the lack of viability of IVF embryos and, if also present in vivo, could explain the lower fertility rates seen in humans when compared to other mammals (10).

Molecular karyotyping by comparative genomic hybridization (CGH) has furthered the ability to assess the frequency and origin of chromosome abnormalities in both oocytes and embryos at various stages of development. This technology permits the assessment of both whole chromosome as well as segmental aneuploidy. However, the need to amplify the DNA from a single cell prior to array comparative genomic hybridization (aCGH) may introduce artifacts. Array-based CGH on human oocytes has demonstrated aneuploidy in 3–65%, depending on the study, age of the mother, and level of maturity (13). CGH following degenerate oligonucleotide primed polymerase chain reaction (DOP-PCR) amplification of the DNA from single blastomeres of 12 human cleavage embryos (12) revealed only 3 to be normal (25%), with 3 (25%) having evidence of meiotically derived aneuploidy (all cells with the same abnormality), and the other 50% showing mosaicism, a postfertilization event. Similarly, Wells and Delhanty (18) reported 75% of 3-day embryos to have chromosome abnormalities with a high percentage of chromosomal mosaicism. Both these early studies reported some “chaotic embryos” in which different chromosome abnormalities were observed in different cells from the same embryo. Using aCGH, Vanneste et al. (19) showed that while only 12.5% of fertilized human oocytes were chromosomally unbalanced, 83% of 3-day embryos showed whole-chromosome aneuploidy. Only 3 of 19 (15.8%) of these embryos showed consistent abnormalities in all blastocysts, compatible with a meiotic origin of the abnormality, while the rest were mosaic. Healthy, cleavage-stage embryos obtained by IVF (for evaluation of X-linked disorders, BRCA2 mutations, or familial microdeletion syndromes, from woman less than 35 years of age, whose partners had a normal semen analysis, and without parental chromosome rearrangements) showed mosaicism in 91% of embryos. Whole-chromosome aneuploidy was observed in 83%, terminal segmental aneuploidy (deletions, duplications or amplifications) in 70% and uniparental disomy (UPD) in 9% (20). A comprehensive series of aCGH studies on 1290 human embryos from women aged 29–50 years (10) demonstrated that 58% of these blastocysts contained chromosome abnormalities. Subsequent single nucleotide polymorphism (SNP) analysis of these embryos revealed that only 43% of these abnormalities (representing 25% of all blastocysts) were due to meiotic errors. Overall, the range of genetic imbalance detected in embryos

by aCGH varies significantly from 12.5% to 83% (15,16,18,19,21,22), possibly a reflection of differences in the maternal populations from whom the embryos were obtained. Analysis of multiple single cells from a single embryo demonstrates a high level of postfertilization instability leading to both mosaicism and the chaotic embryos reported by FISH. Of note, in a majority of cases, embryos with mitotically derived errors (mosaic or chaotic embryos) were less likely to be viable than those with meiotic errors suggesting that many of the mitotic, postfertilization chromosome errors may contribute to infertility and preclinical loss, while the meiotic errors may be more commonly associated with the loss of recognized pregnancies. In addition, aCGH has found more subtle chromosome imbalances in 2 of 11 fetuses (18%) reported to have a normal banded karyotype (21), indicating that even pregnancies reported to be normal and balanced by routine cytogenetics may harbor subtle segmental aneuploidies that contribute to their nonviability.

SNP arrays have been used to evaluate early embryos, and the limited reports using this methodology do not always support the high abnormality rates identified by FISH. A group specifically addressing this question by evaluating the same embryos with both FISH and SNP microarrays (22,23) reported significant discrepancies. In one study on 13 cleavage-stage embryos, nine-probe FISH demonstrated mosaic aneuploidy in 77%, while only 38.5% were abnormal on microarray analysis. In another study, the same group found consistency between FISH and microarray results in less than 50% of samples, with most of the discrepancies being in embryos reported to show monosomy or complex aneuploidy. Another group (24), using a different genome-wide genotyping SNP microarray and software that makes use of parental genotypes to minimize error-prone single-cell microarray data, found aneuploidy rates in early embryos of 20–70% depending on the age of the women from whom the embryos were obtained. Additional use of this approach may also be of value in determining the impact of UPD on pregnancy loss, which to date, has been reported to be infrequent (25).

### 34.3.2 Pattern of Chromosome Abnormalities Seen in Aborted Pregnancies

The vast majority of chromosomal abnormalities observed in aborted fetuses evaluated by G-banding are numerical, including autosomal trisomies, polyploidy, sex chromosome monosomy and double trisomies (26). A 2009 study, combining G-banding with MLPA and aCGH (27) on 115 first-trimester miscarriages, found 69 (60%) to be chromosomally abnormal. Of these, 69% had autosomal trisomy (including 2% with double trisomies), 12% were polyploid (primarily triploidy), and 10% had sex chromosome monosomy (45,X), with only 1% showing structural abnormalities and the rest

showing errors not involving entire chromosomes, such as duplications or deletions. Similar results were reported by combining karyotype analysis with reflex FISH (28), which observed 61% trisomy, 15% polyploidy (primarily triploidy), 14% sex chromosome monosomy and 7% structural abnormalities. It is not surprising that the most common abnormalities seen are autosomal trisomies, as it was recognized as early as 1984 by Hassold and Chiu (5) that the risk of both pregnancy loss and the incidence trisomy as the result of maternal nondisjunction increase with maternal age, and thus are likely to occur concurrently. Our own data (unpublished) shows the most frequent chromosome abnormalities in presumably sporadic fetal losses to be triploidy, sex chromosome monosomy, and trisomies (21, 22, 15, 18, 13 and 16 in descending order (Figure 34-1)). A slightly different pattern was observed among losses from women with a history of pregnancy loss, with the most prevalent abnormalities being triploidy, and trisomies 22, 16, 15 and 21. Interestingly, the pattern associated with sporadic loss is similar to that due to meiotic errors (9), while the pattern seen in the women with recurrent loss has been associated with mitotic errors seen in mosaic IVF embryos. The relative paucity of sex chromosome monosomy among the recurrent losses might be related to the

slightly advanced age (37.3 vs 36.2 years) in this group, as sex chromosome monosomy is most often due to non-disjunction in males, and thus would not necessarily be related to maternal age. Double trisomies, which, except in very rare instances involving the presence of an extra sex chromosome, are not viable, are not uncommon in abortus samples, representing about 1–2% of these cases (29). They are almost always a result of maternal nondisjunction (30) and are also associated with older maternal age. It should be noted that while studies on preimplantation embryos (see earlier) often report autosomal monosomy, peaking at about the eight-cell stage, such karyotypes are inviable, and autosomal monosomy has not been reported in abortus specimens.

### 34.3.3 Association of Advanced Maternal Age and Chromosome Abnormalities in Miscarriage

It is well established that increasing maternal age is the most important etiological factor associated with trisomy in humans. The National Down Syndrome Project (31) showed a significant association between advanced maternal age and trisomy 21 due to both meiosis I and meiosis II errors. This age-related increase in nondisjunction may be

**FIGURE 34-1** Relative frequency of chromosome abnormalities observed in cytogenetically abnormal POCs from women with a reported history of recurrent pregnancy loss compared to those with reported sporadic pregnancy loss. Mean maternal age was 37.3 years in the recurrent group and 36.2 years in the sporadic group. Number of chromosomes involved presented across the X axis with 23=double trisomy, 24=monosomy X, 25=triploidy, 26=tetraploidy. The abnormalities that are considered viable (trisomy 13, 18 and 21 and monosomy X) are all more frequent in the group with sporadic losses, with trisomies 15, 16 and 22 being more prevalent among those with recurrent loss.

due to alterations in the cohesin complex (32,33) or differences in the patterns of recombination (34) during meiosis. Since the incidence of miscarriage also increases with maternal age, going from 10% in women 20–24 years of age to over 90% in women over 45 years of age (35), most pregnancy losses, especially those in older women, are associated with errors due to maternal nondisjunction. Boue and colleagues (36) reported that the mean maternal age of woman whose abortuses demonstrated a chromosome anomaly was increased compared to those with normal fetal results. This is consistent with the increased incidence of autosomal trisomy with advancing maternal age. Hassold and Chui (5) confirm this association, reporting that the rate of trisomies seen in spontaneous abortions is 20% in women under 25 years, 33% for those 30–35 years of age, and at least 67% in women who are 40 or older. Similarly, Fragouli and Wells (10) found that older women had a tendency to generate more chromosomally abnormal blastocysts, with an aneuploidy range of 46.5% in women 34 years of age or younger and 60.6% in women over age 35. In one set of SNP microarray studies cited earlier (22,23), the incidence of fetal aneuploidy increased from 19.6% when the mean maternal age was 31 (range 22–37 years) to 76.9% with a mean maternal age of 38.8 (range 32–44 years). Thus, it can be inferred that most pregnancy losses result from a fetal chromosome abnormality, and that this is particularly true in older women, who comprise a disproportionate number of those experiencing pregnancy loss.

### 34.3.4 Relative Incidence of Chromosome Abnormalities in Sporadic vs Recurrent Pregnancy Loss

Women who experience pregnancy loss usually take longer to achieve their desired family size, and so are often attempting pregnancy at older ages. Thus, the age-related incidence of nondisjunction and associated fetal chromosome abnormalities (see earlier) could be contributing to their unsuccessful pregnancy history. In a case-control study (37) women having experienced two consecutive miscarriages were found to be older than controls, with 42.6% being older than 35 years of age, while in the control group the percentage of women over 35 years was only 13.9. In addition, the risk of repeated miscarriage was threefold higher in women over 35 as compared to those 25–29 years of age. Rubio et al. (38) performed PGD on 71 couples with a history of recurrent miscarriage and a age-matched control group of 28 couples undergoing PGD because of the risk of sex-linked diseases (without other infertility problems) and observed that the couples with recurrent miscarriage produced chromosomally abnormal embryos at a higher rate than those not having this reproductive problem. Marquand et al. (39) evaluated first-trimester losses in 180 women who were over 35 years of age. Of these, 24% had experienced at least three prior losses. In this recurrent loss

group, the incidence of aneuploidy was 78%, which was not statistically different from the 70% aneuploidy rate in the sporadic group. Both groups had similar mean maternal ages. Bianco et al. (40) observed that, the more pregnancy losses a woman had experienced, the greater the likelihood that she would be found to have a fetus with a chromosome abnormality at prenatal diagnosis. In their evaluation of nearly 47,000 women undergoing prenatal diagnosis, the incidence of an abnormal fetal karyotype increased from 1.39% in those with no history of pregnancy loss to 2.18% in those who had three or more losses. Our own data (unpublished) on POC shows the incidence of at least one chromosomally abnormal sample from women where we received at least two POCs was 73.9% compared to the overall abnormality rate of 49.5%. These observations would tend to refute the concept that recurrent pregnancy loss is primarily due to factors other than chromosome abnormalities in the fetus.

### 34.3.5 Parental Chromosome Abnormalities

Although fetal chromosome abnormalities are extremely common in miscarriage samples, most of the abnormalities observed are numerical and *de novo*, and do not necessitate parental chromosome analysis. However, there are situations in which parental chromosome analysis is indicated, as parental balanced chromosome rearrangements can lead to abnormalities in meiosis and the generation of unbalanced gametes.

**34.3.5.1 Structural Rearrangements.** Couples experiencing two to three pregnancy losses are often referred for chromosome analysis, as a vast literature (2,41–46) suggests that in about 5% of these couples, one of the partners will have a balanced chromosome rearrangement (either a translocation or an inversion). Mau-Holzman (47) in a study of the somatic karyotype of infertile men and women found chromosome rearrangements in 4% of men with azoospermia, 24% of men with oligospermia, and 20% of women who were candidates for ISCI, confirming the principle that meiosis in individuals with balanced chromosome rearrangements often generates unbalanced gametes leading to nonviable conceptions associated with either infertility or pregnancy loss. The incidence of parental chromosome abnormalities is lower than this in couples achieving, but subsequently losing pregnancies (48–53), being in the range of 2.7–7.6% (for comparison, the incidence of balanced chromosome rearrangements detected in 269,371 prenatal diagnosis studies was only 0.09% (54) and only 0.2% in a population of phenotypically normal, fertile adult males being tested as sperm donors (52)). Couples with one partner who has a balanced chromosome rearrangement tend to have a very poor pregnancy history, because of the production of genetically unbalanced gametes and fetuses. Sugiura-Ogasawara et al. (42) evaluated couples in which one partner was known to carry a translocation

and observed a pregnancy loss rate of 61% if the translocation was carried by a male and 72% if carried by a female. Thus, some clinicians recommend that these couples undergo IVF with PGD in the hopes of achieving a pregnancy with a balanced karyotype.

**34.3.5.2 Mosaicism.** The empirical risk for recurrence of autosomal trisomy, after a couple has experienced one such pregnancy, is routinely quoted as 1%. Several older studies demonstrated that this 1% recurrence rate may be explained by the presence of parental mosaicism for an autosomal trisomy, including gonadal mosaicism, and that 1% of couples who give birth to a child with an autosomal trisomy demonstrate such mosaicism. Since fetal autosomal trisomy, even those trisomies that are considered viable, is often associated with pregnancy loss, parental mosaicism might contribute to the occurrence of chromosomally abnormal pregnancy losses, especially in couples with recurrent losses. Although there are several isolated reports of the finding of parental mosaicism in couples with a history of pregnancy loss (55–58), Kuo (56) reviewed karyotypes from 1010 couples with a history of recurrent spontaneous abortion (blood lymphocytes and skin fibroblasts) and found only two women (0.2% of couples) who demonstrated mosaicism for chromosome 21. An earlier study, showing that the recurrence of the same chromosome abnormality in subsequent losses (60) did not occur more often than expected by chance, also concluded that the incidence of gonadal mosaicism was low in couples with recurrent

abortion. However, Warburton et al. (61) did find a higher recurrence risk for trisomy 21 mosaicism only among younger mothers with repeat losses, suggesting that in this population, gonadal mosaicism may explain some recurrent losses.

### 34.3.6 Other Causes of Pregnancy Loss

While the single most common reason for the loss of a recognized pregnancy during the first trimester is the presence of a genetically unbalanced fetal genotype associated with an abnormal karyotype, many other factors have also been investigated (Table 34-1). Some women, who experience pregnancy losses, may do so because of underlying maternal diseases, which may be amenable to treatment. Any disease that can potentially decrease uterine-placental blood flow profoundly may be implicated in causing a fetal demise. These could include maternal hypertension, systemic lupus erythematosus (SLE), insulin-dependent diabetes mellitus, sickle-cell disease, renal disease with hypertension, severe maternal trauma, and drug exposure. Women who were themselves exposed to diethylstilbestrol in utero also show an increased incidence of spontaneous abortion, ectopic pregnancies and preterm births, presumably as a result of congenital tubal or uterine abnormalities induced by their exposure to the drug during embryogenesis (62). Unfortunately, many of the studies involving these potential causative factors have investigated the couples

**TABLE 34-1 Evaluation and Management of Recurrent Early Pregnancy Loss**

Etiology	Prevalence (%)	Diagnostic Studies	Treatment
Parental chromosome rearrangement	5–8	Karyotype of both partners	Genetic counseling PGD? Donor gametes?
Uterine anatomy	15–20	HysteroGRAPHY Hysterosalpingography Saline infusion sonohysteroGRAPHY	Hysteroscopic metroplasty Hysteroscopic myomectomy Lysis of adhesions
Immunologic	15–20	Lupus anticoagulant Anticardiolipin IgG/IgM B <sub>2</sub> -glycoprotein-1 IgG/IgM Phosphatidylserine IgG/IgM	Low-dose aspirin Heparin/enoxaparin
Thrombophilia	8–12	Factor V Leiden mutation Prothrombin gene mutation Fasting homocysteine level Antithrombin III activity Protein C activity Protein S activity	Heparin/enoxaparin Folic acid
Endocrinologic	8–12	Midluteal phase endometrial biopsy Midluteal phase progesterone Thyroid stimulating hormone Prolactin level Fasting glucose and insulin	Progesterone Levothyroxine Cabergoline/bromocriptine Metformin/insulin
Microbiologic	8–10	Endometrial biopsy Vaginal/cervical cultures	Appropriate antibiotics
Environmental	5	Review exposure to alcohol, tobacco and caffeine Review exposure to environmental chemicals and toxins	Eliminate exposure

experiencing losses, without appropriate control populations or taking into consideration the chromosomal status of the fetus. Thus, some of the possible causes of pregnancy loss addressed in the prior version of this text (e.g. HLA similarities between parents and skewing of X-inactivation) have since been discredited (63–66), and will not be addressed here. However, in the minority of couples experiencing the loss of chromosomally normal fetuses, these factors can be explored, as potential remedies exist for some.

### 34.3.7 Other Genetic Factors

**34.3.7.1 Single Gene Disorders.** A few single gene disorders have been associated with both early and late pregnancy loss including stillbirth. These include hemoglobinopathies, inborn errors of metabolism and inherited thrombophilias. Most of these disorders are inherited in an autosomal recessive fashion. Thus, consanguinity increases the risk for these disorders in that the likelihood that both parents carry the same autosomal recessive mutation is increased, as a result of “identity by descent.” Alpha thalassemia major is an example of a single gene disorder that can cause pregnancy loss (67,68). Alpha thalassemia causes pregnancy loss when both parents carry complete deletions (null alleles) that are in the cis configuration. This results in deletion of both  $\alpha$ -thalassemia genes on the same chromosome. If the fetus inherits the deleted chromosome from both parents, it will be deleted of all four  $\alpha$ -globin genes, resulting in hemoglobin Barts and hydrops fetalis leading to fetal death in the second and third trimesters. Individuals of Southeast Asian ancestry are at greater risk to carry the cis configuration and to have affected offspring. However, the majority of autosomal recessive disorders are not associated with increased risk for early pregnancy loss.

Most genetics textbooks include a discussion of X-linked dominant disorders, the majority of which are lethal in males, including pedigrees depicting multiple losses of male pregnancies. However, the list of disorders in this group is small (Table 34-2) and the incidence of carriers is very low, so that this is a very infrequent cause of pregnancy loss. For the rare families in this category, PGD may help to achieve a desired family size.

There are limited data to suggest that other familial mutations might increase the risk of pregnancy loss in certain families. Transmission rate distortion has been reported for spinal muscular atrophy (69,70), which could be explained by the early loss of some fetuses homozygous for the mutant allele. A study investigating the incidence of variants of *BRCA2* in newborns (71) found a deviation from the Hardy–Weinberg equilibrium, with reduced fitness for homozygotes with variant alleles suggesting reduced prenatal viability for these genotypes. For individual families, heterozygosity for a common allele in the parents may contribute to recurrent loss, as has been reported in some consanguineous populations (72).

**TABLE 34-2 X-Linked Dominant, Male Lethal Disorders Are Rare**

Disorder/MIM	Incidence
Aicardi 304050	1:93,000–1:167,000
Chondrodysplasia punctata 302960	1–9/1,000,000

Goltz syndrome (focal dermal hypoplasia) 305600	<1/1,000,000 95% new mutations
Incontinentia pigmenti 308300	1–9/1,000,000
Microphthalmia with linear skin defects 309801	<1/1,000,000
Oculo–facio–cardio–dental 300166	<1/1,000,000
Oral–facial–digital type I 311200	1:250,000–1:50,000
Rett 312750	1:8500
Terminal osseous dysplasia 300244	<1/1,000,000
Wildervanck syndrome 314600	?

**34.3.7.2 Thrombophilias.** The thrombophilias are a group of disorders in which there is a propensity to develop venous or arterial thrombosis. Both inherited and acquired thrombophilias and the associated thrombosis of placental vessels have been proposed to influence pregnancy loss (73–75). Mutations in the genes for both factor V and prothrombin have also been associated with unexplained late fetal loss and other thrombosis-related pregnancy complications (76,77). Factor V Leiden (FVL) mutations and the associated resistance to activated protein C are reported to be more prevalent in woman with a history of pregnancy loss in several studies (76,79–86), with an incidence of 7–44% in those with losses as compared to 1.6–6% in controls. Studies on mice, made deficient for factor V through gene targeting, show that half the embryos die during the first half of gestation, probably as a result of abnormalities in yolk-sac vasculature (87). Earlier reports suggested that FVL deficiency is associated with preeclampsia, abruptio placentae, fetal growth restriction, late pregnancy loss and stillbirth. Yet, a number of large collaborative studies have not confirmed this association (88–90). An additional hereditary thrombophilic tendency implicated in recurrent pregnancy loss is hyperhomocysteinemia, which has also been associated with other thrombotic morbidities, such as adult myocardial infarction (91–93). Some reports have shown an association between a homozygous C→T polymorphism at nucleotide 677 in the gene coding for methylenetetrahydrofolate reductase (MTHFR), which leads to a thermolabile variant of the enzyme and low levels of serum folate, hyperhomocysteinemia and early pregnancy loss (91,94,95). The combination of serum folate deficiency and hyperhomocysteinemia has been reported to result in defective chorionic villus vascularization (93) and would be amenable to treatment with relatively high doses of folic acid (5 mg/day) along with pyridoxine supplementation (91). Two meta-analyses

and related studies of thrombophilic disorders and fetal loss showed an association between FVL, activated protein C resistance or the prothrombin G20210A (PGM) mutation and recurrent early fetal loss, but demonstrated no association between the MTHFR mutation and fetal loss (96–98). A combination of heparin or enoxaparin and low-dose aspirin is recommended for treatment of pregnant women with FVL and prothrombin gene mutations (98). This is the current protocol followed at our center.

**34.3.7.3 Autoimmune Disorders.** The presence of autoimmune antibodies, with or without other stigmata of autoimmune disease, has been described as a risk factor for recurrent pregnancy loss. The role of autoimmune antibodies as the cause or result of the pregnancy loss has been influenced by studies of the effect of thrombophilia on pregnancy loss rates (Table 34-3). During pregnancy and the postpartum period, SLE, with a prevalence of

1–1.6% in the female population (99,100), can be associated with a series of remissions and exacerbations with an increased risk of “flares” during pregnancy (101). If the disease is in remission at the time of conception, the fetal survival rate is quite good, about 85% (102), but still below that seen in unaffected women. However, if SLE is active during the pregnancy, particularly if a lupus flare occurs in the first trimester, the fetal survival rate decreases to 50–75% because of complications of placental thrombosis and hypertension (103) associated with lupus flares. Similarly, several connective tissue diseases that produce circulating antibodies, such as Ro (SSA), can lead in utero to complete heart block (104) and pregnancy loss.

**34.3.7.4 Antiphospholipid Syndrome.** The antiphospholipid syndrome involves the presence of a spectrum of antibodies directed against cellular phospholipid components. This syndrome has been associated with arterial and venous thrombosis, recurrent pregnancy loss, and immune thrombocytopenia in the absence of rheumatologic disease. The antiphospholipid syndrome is defined on the basis of clinical and laboratory criteria. The criteria proposed by Laskin et al. (105) are shown in Figure 34-2.

The obstetrical literature reports that certain antiphospholipid antibodies, particularly lupus anticoagulant and anticardiolipin IgG and IgM, are associated with recurrent early pregnancy loss. Elevated levels of both antiphospholipid antibodies (lupus anticoagulant) and anticardiolipin IgG and IgM have been reported in women with a history of pregnancy loss (106). Both these classes of antibodies lead to a higher incidence of thrombotic events (lupus anticoagulant interferes with the conversion of prothrombin to thrombin), causing placental thrombosis and infarction (107). Thus, while the presence of these antibodies has been associated with

**TABLE 34-3 Factors that Contribute to Vascular Problems in the Placenta**

Clotting factors	Factor V Leiden Factor XII Protein C Prothrombin
Metabolic problems	Hyperhomocyst(e)inemia Methylenetetrahydrofolate reductase deficiency
Other	45,X karyotype

#### Clinical Criteria

Vascular thrombosis

Adverse pregnancy outcome

- At least one unexplained pregnancy loss after 10 weeks GA
- Three or more unexplained, consecutive pregnancy losses before 10 weeks GA
- One or more preterm births of a normal neonate at or before 34 weeks GA because of preeclampsia, eclampsia or placental insufficiency

#### Laboratory Criteria

Moderate or high titer IgG or IgM anticardiolipin antibody measured on two or more occasions at least 6 weeks apart

Circulating anticoagulant measured on two or more occasions at least 6 weeks apart

**FIGURE 34-2** Criteria for classification of antiphospholipid syndrome.

pregnancy loss in any trimester, most of the losses occur later in pregnancy (108). Antiphospholipid antibodies were detectable in 16% of patients with three or more pregnancy losses as compared with 7% of normal controls, and in only 3% of women who had never reported a pregnancy (109). Creagh et al. (110) reported the incidence of women with lupus anticoagulant or anticardiolipin as 7/35 and 6/35, respectively, in a group with more than two losses, as compared to 1/31 and 0/31 in a group with two or fewer losses. However, low-positive IgG fractions of antiphospholipid antibodies or isolated IgM fractions do not establish a diagnosis of the antiphospholipid syndrome. Women with prior fetal losses and high levels of anticardiolipin IgG antibodies appear to be at the highest risk of fetal loss in subsequent pregnancies and may benefit the most from preventive therapies (111). An elevation of antinuclear antibodies occurred in the sera of a woman with previous pregnancy loss, even when the loss had been explained by other causes such as anatomic or luteal phase defects (LPD) (112). However, antinuclear antibodies alone appear to be nonspecific markers in women with pregnancy loss, with other investigators demonstrating no difference in the proportion of positive antinuclear antibody tests between women with recurrent losses and appropriate controls (112). Takakuwa et al. (113) observed that the incidence of chromosomally abnormal abortuses was lower in woman with elevated anticardiolipin antibodies (20% as compared to 60% in controls), suggesting that some of their losses were not due to chromosome abnormalities, but associated with this autoimmune phenomenon. Whether some of these autoimmune antibodies are generated in response to fetal demise in susceptible women rather than being the cause of the pregnancy loss has been cause for speculation. However, immunoglobulin isolated from women with elevated anticardiolipin levels can induce abortion in pregnant mice (114), suggesting that the antibodies themselves may be the underlying etiology of the loss. In addition, several studies have suggested the use of corticosteroids, heparin, aspirin, and immunoglobulin therapy in preventing pregnancy loss in women with antiphospholipid antibodies (108–118). Controlled trials have confirmed the efficacy of low doses of aspirin and/or heparin (119–121). Interestingly, the efficacy of heparin may be due to its inhibition of complement activation rather than its anticoagulant effects (122). Other antiphospholipid antibodies such as antiphosphatidylserine and  $\beta_2$ -glycoprotein-1 may be associated with recurrent pregnancy loss. However, the evidence for this association is weak (123).

**34.3.7.5 Endocrine Disorders.** A number of maternal endocrine disorders have been linked to pregnancy loss.

**34.3.7.5.1 Diabetes Mellitus.** In nonpregnant women of child-bearing age, the term type I diabetes is used to include all insulin-dependent diabetes, while type II diabetes implies non-insulin-dependent disease. In pregnancy, classification is based on whether or not

a woman has had diabetes prior to pregnancy. Pregestational diabetes is then subdivided into alphabetical classes depending on the age of onset, duration of the disease, or both and whether any diabetic vascular complications occurred. Gestational diabetics have diabetes only during pregnancy and are classified as A1 if controlled with diet only, and A2 if insulin is needed (124). Even prepregnancy obesity, possibly through its association with insulin resistance and the metabolic syndrome, has been associated with an increase in stillbirths and neonatal deaths (125). Poorly controlled diabetes mellitus is known to cause miscarriage. Elevated glycosylated hemoglobin levels associated with poor glycemic control in early pregnancy are associated with spontaneous abortion. In contrast, the risk for pregnancy loss is not increased in women with well-controlled diabetes (126). Metabolic control of diabetes prior to conception and during the first trimester dramatically influences both the risk of spontaneous abortion and the incidence of major congenital anomalies (126,127). The perinatal mortality rate of about 3% in well-controlled diabetic women has been stable for over 30 years (128), with associated elevated risks for preeclampsia and preterm delivery. Poorly controlled diabetes is associated with an even higher perinatal death rate (129). Excluding lethal fetal anomalies, maternal complications of ketoacidosis, pregnancy induced hypertension (PIH), pyelonephritis, or neglect increase the perinatal mortality rate to as high as 17% (130). Preeclampsia was diagnosed in about 12.7% of diabetic women and preterm labor in 32% (125). Major congenital anomalies were increased threefold in diabetic pregnancies, but excellent prepregnancy control can markedly reduce the incidence of malformations (126,128). In a recent outcome survey of 273 women with type I diabetes, although the congenital abnormality rate was twice that seen in the general population, the rate of miscarriage was 14.7%, which is within the background rate (125,131). Even elevated maternal weight, which may be associated with type II diabetes, has been implicated as a risk factor for pregnancy loss (132). Early detection, excellent control, fetal surveillance, and blood pressure monitoring are key factors in lowering the perinatal mortality rate associated with maternal diabetes.

**34.3.7.5.2 Luteal Phase Defect.** During the luteal phase of the menstrual cycle, the corpus luteum produces progesterone, which induces the secretory changes in the endometrium that are necessary for implantation and maintenance of pregnancy. Once pregnancy occurs, the corpus luteum continues to secrete progesterone until the placenta produces enough progesterone to maintain the pregnancy.

LPD is defined as a lag of more than two days in the histological development of the endometrium compared with the day of the menstrual cycle. This retardation in endometrial development in the peri-implantation period may be associated with recurrent miscarriage. However,

many studies of this phenomenon have not included concurrent controls, and normal women can have endometrial histology suggestive of LPD in up to 50% of menstrual cycles, suggesting that the association between LPD and recurrent pregnancy loss remains speculative.

A midluteal phase serum progesterone of <10 ng/mL is considered to be diagnostic of an inadequate luteal phase. Uncontrolled studies suggested that treatment with progesterone improves pregnancy outcome in women with recurrent miscarriage. However, several meta-analyses of controlled trials revealed no statistically significant difference in miscarriage rate between progestins and placebo or no treatment (133). Well-designed randomized trials are needed to establish the efficacy of progesterone supplementation in the treatment of recurrent early pregnancy loss.

**34.3.7.5.3 Thyroid Disorders.** Clinical hypothyroidism and hyperthyroidism have both been associated with decreased fertility and increased pregnancy loss rates. In particular, untreated or inadequately treated hypothyroidism has been associated with an increased risk for spontaneous abortion (134). Subclinical thyroid dysfunction, however, has not been linked to pregnancy loss (134,135). Antithyroid antibodies are more frequent in women with recurrent pregnancy loss, although, if the patient is clinically euthyroid, the presence of antithyroid antibodies does not appear to influence pregnancy outcome (136). In patients with clinical hypothyroidism, treatment with thyroxine, and subsequent restoration of normal thyroxine levels, reduces the risk for pregnancy loss.

**34.3.7.5.4 Hyperprolactinemia.** Hyperprolactinemia has also been suggested as a cause of miscarriage by affecting the hypothalamic–pituitary axis and causing inadequate oocyte maturation and luteal phase deficiency. However, evidence from controlled studies to support this theory is lacking. In an observational study involving 54 hyperprolactinemic women who underwent 64 pregnancies, Crosignani et al. (137) reported a miscarriage rate of 25%. In a series of 64 women with hyperprolactinemia who underwent 103 pregnancies (78 treated with bromocriptine and 25 untreated), Rossi et al. (138) reported an increased rate of ectopic pregnancy in the untreated group (24% vs 5%,  $p < 0.02$ ) but no increase in rate of spontaneous abortion. However, in one study involving 64 women with hyperprolactinemia among 352 women with recurrent pregnancy loss, treatment of hyperprolactinemia with bromocriptine was associated with a decrease in the rate of recurrent pregnancy loss (139).

**34.3.7.5.5 Polycystic Ovarian Syndrome.** Polycystic ovarian syndrome has also been investigated in women with recurrent spontaneous abortions (140). Over 40% of women with recurrent loss demonstrated features consistent with polycystic ovarian syndrome. However, as the successful pregnancy rate in these women was similar to that of normal controls, it is

unlikely that this disorder is related to pregnancy loss in ovulatory women.

**34.3.7.6 Nongenetic Factors.** Pregnancy losses beyond the first or early second trimester have been associated with nongenetic factors such as maternal structural anomalies, infection or trauma.

**34.3.7.6.1 Uterine Anomalies.** Defects caused by abnormal Müllerian fusion are a recognized cause of pregnancy loss. The presence of an intrauterine septum has been associated with recurrent early pregnancy loss. However, other Müllerian anomalies such as bicornuate and unicornuate uterus have been associated with second-trimester losses or preterm delivery rather than first-trimester losses (141). Observational studies suggest that surgical resection of intrauterine septae is associated with improved pregnancy outcome. Lin et al. (141) reported a study involving 36 women who had complete uterine septae with double cervix and vaginas. Twenty-one women who underwent hysteroscopic metroplasty were compared with 15 women who had no treatment. The rate of spontaneous abortion prior to the study was similar in both groups. The spontaneous abortion rate in the subsequent pregnancy was 11.1% in the metroplasty group and 87% in the no treatment group ( $p = 0.03$ ) (141). Women with uterine leiomyomata have been reported to be at increased risk for second-trimester spontaneous abortion (142,143). Submucous myomata can result in distortion of the uterine cavity and have been associated with recurrent pregnancy loss in observational studies. A recent meta-analysis showed no significant benefit from hysteroscopic myomectomy in women with submucous myomas (relative risk (RR) = 1.6; 95% confidence interval (CI) = 0.7–3.6) (144). Endometrial polyps and intrauterine adhesions or synechiae (Asherman syndrome) secondary to uterine curettage, particularly in the presence of endometritis, have been associated with recurrent pregnancy loss in uncontrolled studies. Hysteroscopic polypectomy and lysis of adhesions has been reported to be associated with improvement of fertility in patients undergoing IVF (144,145). However, to date, there are no controlled studies demonstrating a reduction in recurrent early pregnancy loss rates with hysteroscopic polypectomy or lysis of adhesions. Structural defects of the uterus have been reported in 15–30% of women who habitually abort as compared to 0.5–2% of normal controls (146), and sonohysterography of woman with at least two prior losses revealed intrauterine abnormalities in 50% (147), suggesting a causal relationship. Surgical correction of uterine abnormalities may be a reasonable option if other causes of recurrent pregnancy loss have been excluded. It is reported that 82% of patients with histories of recurrent loss, who underwent surgical correction of a septate uterus, delivered viable infants in their subsequent pregnancies (148). Cervical insufficiency (incompetent cervix) has been associated with preterm labor and pregnancy loss. Classically, cervical insufficiency presents as painless dilation

without labor, resulting in bulging of the fetal membranes into the vagina. Subsequently, the membranes can rupture and cause expulsion of a previable fetus. This condition, when diagnosed, is amenable to treatment by cerclage. Historically, the necessity of this procedure has been controversial (149). A recent meta-analysis of five randomized trials found that composite perinatal mortality and morbidity were significantly reduced (15.6% vs 24.8%) in women with previous spontaneous preterm birth and short cervix (<25-mm length by vaginal ultrasound) who were treated with cerclage (150). The recognition of a treatable anatomic abnormality often terminates the search for other causes of pregnancy loss.

**34.3.7.6.2 Infectious Agents.** Pregnancy-related infections are uncommon, but have been reported to be a cause of fetal loss. Mumps and measles, when acquired during pregnancy, have been associated with increased rates of spontaneous abortion (151). Other maternal infections, such as cytomegalovirus (CMV), parvovirus B-19 and syphilis, can result in second- or third-trimester fetal death (152,153) because of the sequelae of overwhelming fetal infection. A few other bacterial and protozoan microorganisms have been associated with spontaneous abortion including *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Brucella abortus*, *Salmonella typhi*, *Vibrio fetus*, *Chlamydia trachomatis*, and *Toxoplasma gondii*. Transplacental infection has been reported with each of the above agents, making them a possible cause of miscarriage. However, in a study of 818 women enrolled in the early first trimester, Simpson et al. (154) found no difference in clinical infection among 112 women who had pregnancy losses compared with 702 women who had successful pregnancy outcomes. In addition, in a study of 54 chromosomally normal abortuses, PCR of CV showed no evidence of *U. urealyticum*, *M. hominis*, CMV or adenovirus, while eight specimens revealed human papilloma virus and one specimen showed *C. trachomatis* (155).

Other infectious diseases, such as rubella and varicella (156,157), may produce a substantially increased risk of structural fetal abnormalities, or developmental abnormalities, such as CMV, without intrinsically increasing risk of fetal loss (158).

**34.3.7.6.3 Teratogens.** Exposure to teratogenic agents during pregnancy is known to produce abnormalities of form or function, including fetal wastage. The pathogenetic mechanisms leading to fetal death may occur through disturbance of one or more developmental processes. These include hypoplasia or hyperplasia of developing tissues, failure of cell differentiation, interaction or migration, or mechanical disruption of cells. Often, the end result of teratogenic action is an organ with too few cells. Subsequently, the organ system may fail to develop fully because of a lack of critical mass required for differentiation. Pregnancy loss due to teratogenetic agents is often difficult to prove conclusively, and many relatively safe agents have been incorrectly implicated from anecdotal experience. Gardella and Hill (159)

reported that the only teratogens that are convincingly associated with pregnancy loss are ionizing radiation (the Hiroshima experience), organic solvents, alcohol, mercury and lead, with some additional data implicating cigarettes. However, the majority of known teratogens are not associated with an outcome as severe as fetal death. Table 34-4 lists agents that include pregnancy loss as part of their related effects. Certain classes of drugs, such as folic acid antagonists (aminopterin and methotrexate) are well-documented abortifacients and have been specifically studied in terms of the timing and dose required for subsequent fetal wastage (160). Cancer during pregnancy is a rare occurrence, with an incidence of about 0.04% (161). The most common malignancies include those of the breast, cervix, thyroid, ovary, and lymphoma. Pregnancy outcome appears to be extremely good in women with hematological malignancies (162). Chemotherapy in the first trimester has been associated with an increased incidence of abortion and fetal abnormalities (163). Antineoplastic agents in general raise serious concerns regarding the mutagenic, teratogenic, and abortifacient effects on the human embryo. However, with the exception of aminopterin and methotrexate (160), individual agents have not been sufficiently studied to determine whether a clear risk for pregnancy loss exists.

**34.3.7.6.4 Maternal Stress.** Maternal psychological stress has been considered to be a risk factor for early pregnancy loss. However, scientific evidence to support the association between stress and miscarriage is sparse. In a study comparing urinary cortisol levels during the first 3 weeks post conception between 9 women who carried to term and 13 women who miscarried, Nepomnaschy et al. (164) found higher mean cortisol levels in the women who miscarried (RR=2.7 (95% CI=1.2–6.2)). They concluded that increased levels of

cortisol serve as a stress marker for higher risk for pregnancy loss. Several studies have reported that supportive care in early pregnancy for women with a history of recurrent spontaneous abortion resulted in a reduction in risk for subsequent pregnancy loss (165,166). For women whose losses were not attributable to identifiable pathology, Clifford et al. (166) reported a rate of successful outcome in the next pregnancy of 69%. This was compared with a successful pregnancy rate of 49% for the women who did not attend the clinic for early supportive care. In the subgroup of women with favorable prognostic features (age less than 40; less than six prior losses), the success rate in the next pregnancy was 79%. Medical therapy and other interventions are often prescribed for women with recurrent losses even in the absence of underlying causes in an attempt to improve outcomes of subsequent pregnancies.

Based on the above findings, women without underlying pathology can be counseled that the outcome for the next pregnancy is likely to be favorable with supportive care alone.

**34.3.7.6.5 Maternal Trauma.** Trauma during pregnancy is not an uncommon occurrence. Approximately 6–7% of pregnancies are affected by some degree of traumatic injury. These injuries are usually accidental but may be a result of intentional violence (167). Trauma is one of the leading causes of maternal death, accounting for up to 46% of cases (168). Factors that predict fetal loss in the face of maternal trauma include the severity of injury, maternal acidosis, hypoxia, shock, severe head injury, direct uteroplacental injury, placental abruption, coagulopathy and maternal death (169). Most studies reporting pregnancy loss rates following maternal trauma have involved perinatal losses in the late second and the third trimesters. There are very limited data regarding maternal trauma and risk for early pregnancy loss. With respect to intentional trauma, Nelson et al. (170) reported the results of a nested case-control study involving 392 women who experienced spontaneous abortion prior to 22 weeks and 807 controls who carried their pregnancies beyond 22 weeks. The authors were unable to demonstrate a relationship between any measure of physical violence and spontaneous abortion. Despite these findings, domestic violence is an important problem. More than 40% of women of reproductive age have experienced at least one episode of violence in their lifetime. As such, domestic violence is a very prevalent and alarming public health issue.

## 34.4 LATE PREGNANCY LOSS

Second- and third-trimester pregnancy loss, although much less common than first-trimester miscarriage, is still a very important event in a woman's reproductive history. A number of retrospective studies have shown an association between prior second-trimester loss and

increased risk for spontaneous preterm birth and recurrent second-trimester loss in subsequent pregnancies (171–173). In some studies, second-trimester losses are classified along with those that occur in the first trimester. However, it is important to recognize that the causes for loss in later pregnancy are often distinctly different from those observed in the first trimester. Factors associated with late pregnancy loss include fetal structural anomalies (including cytogenetic abnormalities), maternal anatomic abnormalities, abnormal first- or second-trimester serum screening results, infection, and inherited thrombophilias. Late losses generally include those occurring after 14 weeks of gestational age because miscarriages that occur before 14 weeks frequently reflect a fetal death that happened a week or two earlier (174).

### 34.4.1 Chromosome Abnormalities

Although 60–80% of first-trimester losses are the result of a chromosome abnormality, only 10–24% of second-trimester losses and 5% of third-trimester stillbirths are associated with chromosome abnormalities (175,176). In contrast, the incidence of chromosome abnormalities in live births is 0.5–0.6% (177). The types of cytogenetic abnormalities found in second- and third-trimester losses are similar to those seen in live births. The most common chromosome abnormalities observed in late pregnancy losses are trisomy 13, 18, 21, and monosomy X and other sex chromosome aneuploidy.

### 34.4.2 Maternal Anatomic Abnormalities

As stated earlier, uterine abnormalities have been associated with an increased rate of pregnancy loss. These losses generally occur in the second trimester or result in preterm delivery (141). These abnormalities, including Müllerian anomalies, cervical insufficiency and uterine leiomyomata, are discussed in greater detail earlier in this chapter.

### 34.4.3 Abnormal Serum Markers

First- and second-trimester serum biochemical markers are widely used to screen for fetal aneuploidy. In the first trimester, low levels of pregnancy-associated plasma protein A (PAPP-A) and free beta-human chorionic gonadotropin ( $\beta$ -hCG) with or without increased nuchal translucency (NT) thickness in the presence of a normal fetal karyotype, have been associated with increased risk for second- and third-trimester pregnancy loss (132,178–180). In a series of 7932 patients undergoing first-trimester screening, Goetzl et al. (178) observed a pregnancy loss rate prior to 20 weeks gestational age of 1.4% for women with multiple of the median (MoM) values for PAPP-A below the fifth percentile compared with 0.36% for MoM values in the normal range (adjusted

odds ratio (OR)=2.8). With respect to second-trimester serum analyte screening, a study involving over 77,000 women showed that those with very low (<0.25 MoM) maternal serum alphafetoprotein (MSAFP) levels had increased risk for spontaneous abortion (RR=12.5), preterm birth (RR=4.8), low birth weight (RR=5.8) and neonatal death (RR=1.9). Likewise, women with very high MSAFP levels (>2.5 MoM) also had increased risk for spontaneous abortion (RR=15.1), preterm birth (RR=2.2) and stillbirth (RR=4.0) (181). There are no proven interventions to prevent adverse outcomes for women who are at increased risk based on abnormal maternal serum screening values or NT measurements. Current data suggest that women with serum analyte and NT values in the screen-negative range can be reassured that the risks for adverse pregnancy outcome are low (178,180,181).

#### 34.4.4 Thrombophilic Disorders

As discussed earlier, in a number of observational and retrospective case-control studies, the thrombophilias and antiphospholipid syndrome have been associated with placental insufficiency and increased risk for adverse pregnancy outcome. Several of these studies have shown an association between FVL and PGM mutations and second- and third-trimester stillbirth (98,182–184). In a prospective cohort study involving 67 women with antenatal fetal death, Simchen et al. found that 33 women (49.3%) had evidence of a placental cause for fetal death (fetal growth restriction, oligohydramnios, placental abruption, and/or histological placental abnormality). Thirty-six of the 67 women (53.7%) tested positive for at least one of the following thrombophilias: FVL, PGM or C677T MTHFR (182). In a retrospective study of a cohort of 363 women with three or more consecutive early or late pregnancy losses, Lund et al. (185) found that the unadjusted live birth rate in the subsequent pregnancy was 46% in carriers of FVL or PGM mutations versus 63% in noncarriers of these mutations ( $p=0.04$ ). However, after adjusting for significant covariables, they found that this difference was no longer significant (185). In a systematic review and meta-analysis of 10 prospective cohort studies, Rodger et al. (184) found that women with FVL had an absolute risk of 4.2% for late pregnancy loss (OR=1.52). Thus, it appears that women with FVL or PGM mutations have an increased relative risk for adverse pregnancy outcome including fetal death. However, the absolute magnitude of this increased risk is small.

#### 34.4.5 Infection

Although infection does not appear to be a common cause of early pregnancy loss, there are data that suggest that maternal–fetal infection is associated with pregnancy

loss in the second and third trimesters. A number of studies implicate bacterial colonization of the lower and upper genital tract as a cause of a significant proportion of preterm births (186–189). Approximately 10–12% of all births in the United States are preterm (<37 weeks gestation). Nearly half of all preterm births are associated with spontaneous preterm labor and approximately a third result from premature rupture of membranes (186). An inverse relationship between the percentage of positive chorioamnion bacterial cultures and gestational age at delivery has been observed (190). In addition, positive chorioamnion cultures have been reported in 73% of women with spontaneous delivery prior to 30 weeks compared with 21% in women with clinically indicated delivery prior to 30 weeks (190). Amniotic fluid levels of proinflammatory cytokines, particularly interleukin-6 (IL-6), have been shown to be higher in women with spontaneous preterm delivery than in those with indicated preterm delivery (191,192).

Bacterial vaginosis (BV) is a condition characterized by overgrowth of gram-negative and anaerobic bacteria resulting in a decrease in the number of beneficial hydrogen peroxide producing *Lactobacillus* species. The most common organisms seen in BV include *Gardnerella vaginalis*, *Bacteroides* sp., *M. hominis*, and *U. urealyticum*. Studies have demonstrated a twofold increased risk of spontaneous preterm birth among women with BV (186,193). In a prospective cohort study involving 1916 pregnant women, Nelson et al. (189) found a twofold increased risk of second-trimester pregnancy loss in women with high levels of BV-associated organisms and low levels or absence of vaginal *Lactobacillus* sp. in the first trimester. Although the presence of BV is a risk factor for late pregnancy loss, it is important to recognize that not all women with BV have upper genital tract infection. In fact, the majority of pregnant women with BV actually deliver at term and clinical trials involving treatment for BV in women with this condition have not shown a decrease in the rate of preterm labor or delivery (194).

Viral infection, particularly with CMV and parvovirus B-19, has been associated with increased risk for second-trimester pregnancy loss (151,195,196). Johansson et al. (196) analyzed blood samples from women taken in early pregnancy for the presence of parvovirus B-19 and herpes viruses. They found that 11 of 234 women (4.7%) who had second-trimester losses and 10 of 270 women (3.7%) who had preterm birth (prior to 32 weeks) had parvovirus B-19 viremia. This was compared with parvovirus B-19 viremia in 5 of 294 (1.7%) women who delivered at term. These findings corresponded to adjusted odds ratio of 3.76 for second-trimester miscarriage and 2.66 for preterm birth <32 weeks. Data such as these suggest that women with viremia in early pregnancy have increased risk for late pregnancy loss. However, more data are needed to confirm this association (196).

### 34.4.6 Recurrent Loss

While pregnancy loss itself is not uncommon, recurrent pregnancy loss, often defined as three or more losses, only affects 1–2% of couples (197), but may suggest some underlying mechanism. These are the families that most often seek medical intervention and make up a large proportion of those being studied to determine underlying causes of pregnancy loss. Empirical data shows that a history of pregnancy loss increases the risk of miscarriage at subsequent pregnancies (1,132), with the risk increasing from 12% without any prior history to 24% after one loss, 32% after three losses and 53% after six or more losses. This supports the idea that in some couples, it is not chance alone that is responsible for an unsuccessful pregnancy history. Although the likelihood of a successful pregnancy for such couples is generally better than 60% (197,198), many seek medical assistance to identify the issues involved, in the hopes of determining a strategy to alleviate the problem. There have been numerous possible causes of recurrent pregnancy loss investigated, and while the literature on this subject is very extensive, many of the proposed causes of recurrent miscarriage have not been substantiated by carefully controlled research, including some of those that have become part of clinical practice in some arenas.

The majority of studies of couples with recurrent pregnancy loss have reported the same risk factors as demonstrated for sporadic losses. As mentioned earlier, the incidence of fetal chromosome abnormalities and the types of abnormalities observed are also very similar, although several studies have shown a higher incidence of chromosome abnormalities in abortuses from women with a history of pregnancy loss, possibly correlated with the older maternal ages in this group. Parental chromosome rearrangements and other genetic factors (discussed earlier) can lead to recurrent fetal loss in individual families, while parental mosaicism is likely to be more of a factor for young women with recurrent loss. Yet, the most consistent difference observed between women with sporadic vs recurrent pregnancy loss appears to be maternal age and a history of prior loss.

Factors that do seem to influence recurrence risks include loss of a chromosomally normal fetus (199), loss after the first trimester, a history of preterm deliveries, infertility problems (200), and younger maternal age (165,200,201). In a Danish study of all reported pregnancies between 1978 and 1992, the overall rate of spontaneous pregnancy loss was reported to be 13.5%, similar to most other studies (201). Within this study, the rate of spontaneous loss in women aged 20–24 years was only 8.9%, while the rate of loss at age 42 was 50%, with nearly 75% of pregnancies in woman 45 years of age and older resulting in a spontaneous loss. A high rate of loss in older women, about 50% in women over 40, was confirmed in another study (165). Ironically, as a woman's age at each subsequent pregnancy is more advanced, failure

to achieve successful pregnancies, and the delay involved, can contribute to the risk of loss. As seen earlier, increasing maternal age is accompanied by a higher likelihood of a chromosomally abnormal fetus, which may then be the explanation for subsequent losses. It is significant that younger women (<35 years of age) with recurrent pregnancy loss tend to have a lower frequency of chromosomally abnormal fetuses than age-matched peers with a single pregnancy loss (35). Thus, in these younger women with recurrent spontaneous abortions the investigation of other explanations of pregnancy loss is warranted. Other possibilities include endocrine/endometrial abnormalities, uterine structural abnormalities, thrombophilic disorders, immune disorders, and occasionally parental chromosome rearrangements or other genetic disorders.

## 34.5 EVALUATION AND MANAGEMENT OF RECURRENT ABORTION

Evaluation of a couple with recurrent pregnancy loss begins with a detailed history, physical examination and appropriate diagnostic studies. The history should include the pattern and gestational age at the time of each prior loss. Gestational age at the time of loss should be confirmed, if possible, by ultrasound, serum hCG results and embryo/fetal pathology. If available, prior cytogenetic results are useful to determine whether the previous losses were due to a structural or numerical chromosome abnormality. The review of systems should include an assessment of endocrinologic and immunologic disorders. Physical examination and laboratory evaluation should be directed toward detection of parental balanced structural chromosome abnormalities, uterine anatomical abnormalities, endocrinologic disorders, immunologic disorders, microbial infection, and inherited thrombophilias. Once etiologic factors are identified, a plan of management should be implemented based on current scientific evidence. A suggested plan for evaluation and management of recurrent early pregnancy loss is shown in Table 34-1.

Psychologic support is often needed for couples with recurrent pregnancy loss. Recurrent miscarriage may lead to feelings of anger, guilt and depression. It may be helpful to refer couples for grief counseling or to suggest that they participate in support groups before attempting a subsequent pregnancy. As noted earlier, supportive care and close monitoring of subsequent pregnancies has been reported to be associated with a greater likelihood of successful outcome.

## 34.6 CONCLUSIONS

Pregnancy loss, particularly when it is recurrent, is an important problem for patients and their clinicians, largely because of the variety of factors that have been proposed to be involved, although only a few of these have been confirmed by evidenced-based investigation (Table 34-5). The single most common cause of

**TABLE 34-5 Factors Definitively Associated with Early Pregnancy Loss**

Unbalanced karyotype in fetus	>60%
Parental chromosome rearrangement	5%
Mendelian disorder in fetus	Rare—family dependent
Uterine abnormalities	~20–75%
Diabetes mellitus (poorly controlled)	RR = 1.9–5.8

pregnancy loss is the presence of a chromosome abnormality in the fetus, particularly if the loss occurs early in the pregnancy. As these abnormalities are the result of random events that occur during meiosis and are highly correlated with maternal age, little follow-up or intervention may be indicated for these women, other than the reminder that as a woman ages, her risk of both chromosomally abnormal fetuses and pregnancy loss will increase. Therefore, karyotype analysis of POC should be a critical part of the evaluation of pregnancy loss, as the observation of a fetal chromosome abnormality would usually preclude the need for additional investigation. It would also serve to identify that population of woman with chromosomally normal fetal losses, in whom other factors may be contributing to recurrent pregnancy loss and in whom additional studies are indicated. These could include investigation of uterine abnormalities and evaluation of antiphospholipid antibodies or conditions that predispose to thrombosis, where potential therapies exist. Limiting clinical research studies to women in this population group should facilitate the evaluation of the efficacy of various therapeutic interventions. In the small population of couples in which parental chromosome abnormalities or other genetic disorders are detected, IVF and preimplantation prenatal diagnosis may help the couple achieve a successful pregnancy outcome. Predicting the likelihood of a successful pregnancy in a couple with recurrent pregnancy loss is complex. Factors to consider are the number of prior losses, the gestational age at the time of loss, cytogenetic findings, the patient's medical history, and results of appropriate diagnostic studies. As noted earlier, if no underlying factors are discovered, many couples will eventually have a successful pregnancy with supportive care alone. The temptation to prescribe unproven treatments should be resisted, even if the couple is highly motivated and willing to "try anything." Careful monitoring of the patient's emotional status is important because patients with recurrent pregnancy loss often experience anxiety, anger and depression. Referral for grief counseling or psychiatric care should be individualized based on the patient's level of well-being.

## A Clinical Approach to the Dysmorphic Child

*Kenneth L Jones and Marilyn C Jones*

Department of Pediatrics, University of California, San Diego, CA, USA

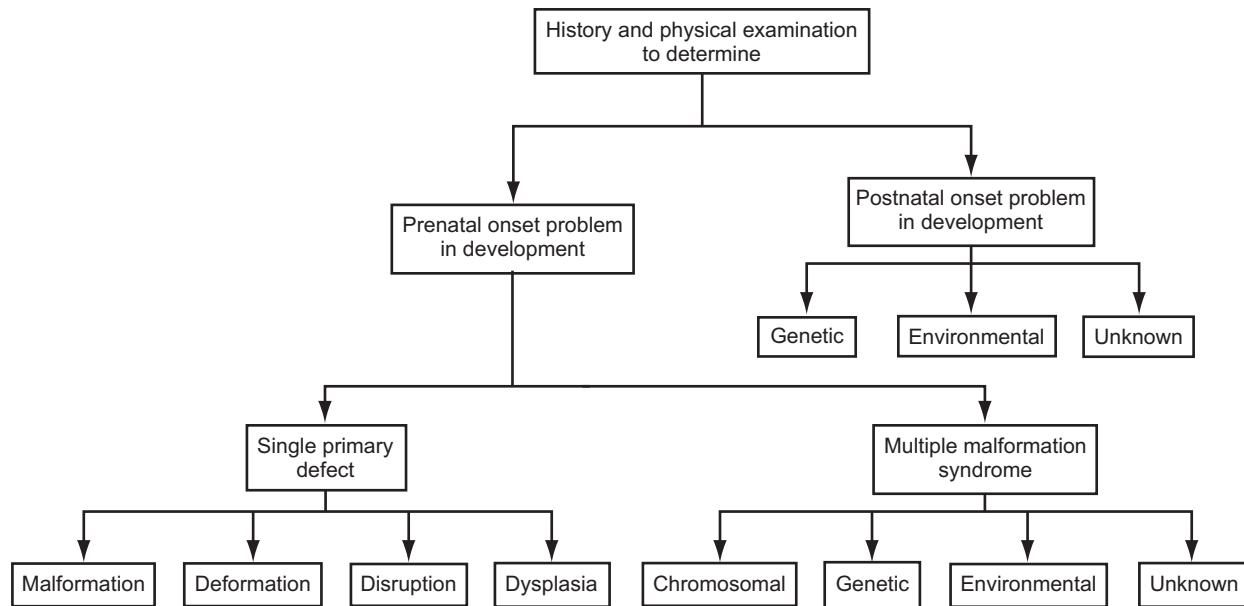

### 35.1 INTRODUCTION

The purpose of this chapter is to present a clinical approach to the child with structural defects. The approach is predicated upon the concept that the nature of the structural defects presents clues to the time of onset, mechanism of injury, and probable etiology of the problem, all of which determine the direction of the evaluation. It presumes that the dysmorphic child represents an experiment in human development, which, if interpreted correctly, can provide answers regarding the etiology of various structural defects, as well as permit insights into mechanisms of normal and abnormal morphogenesis. The method upon which this approach is based has been most articulately set forth by Sir Arthur Conan Doyle's fictional character Sherlock Holmes, who showed "how much an observant man might learn by accurate and systematic examination of all that came within his way" (1). This chapter adapts this method to the evaluation of the child with structural defects. By sharpening the faculties of observation, the clinician can narrow systematically the diagnostic possibilities so that the laboratory and the literature can be consulted in a rational fashion to arrive at an accurate diagnosis. The precise cause of many malformations and malformation syndromes is not known. However, careful clinical evaluation in combination with an expanded range of cytogenetic and molecular testing has allowed the elucidation of the mechanism underlying a growing list of clinical disorders. The separation between genetic and environmental factors as well as cytogenetic and single-gene abnormalities is somewhat arbitrary. However, the approach is intended to be practical and to facilitate detection and prevention of human malformations. *Gorlin's Syndromes of the Head and Neck* (2) and *Smith's Recognizable Patterns of Human Malformation* (3) are particularly useful. In recent years, computerized databases available online and on CD ROM have become useful adjuncts to diagnosis (London Dysmorphology Database (4); Possum Web (5); Online Mendelian Inheritance in Man (OMIM) (6)).

### 35.2 PRENATAL VERSUS POSTNATAL ONSET OF DEVELOPMENTAL PROBLEMS

A method of approach to children with structural defects is set forth diagrammatically in [Figure 35-1](#). Although the lists of exceptions is growing, a history and physical examination usually make it possible to determine if the structural abnormality is of prenatal or postnatal onset. In this chapter, "prenatal onset" designates structural abnormalities that are present at birth, and "postnatal onset" designates structures that have previously developed and differentiated normally. Although the genetic alteration responsible for many of the disorders included under postnatal-onset structural defects is present at the time of conception, the structural manifestations of that genetic alteration do not become obvious until postnatal life. On the basis of this distinction, a more rational approach to the problem can be developed, as this determination narrows considerably the diagnostic probabilities and, it is hoped, permits a more judicious selection of adjunctive laboratory tests.

Generally speaking, prenatal-onset problems in development are a consequence of genetic or chromosomal alterations that cause programming problems in the development and/or differentiation of structure or are the result of factors unique to the pregnancy itself, such as environmental agents, abnormalities of placentation, or mechanical constraint. Although always evident at birth, most prenatal-onset problems remain static or improve postnatally without evidence of neurologic deterioration. By contrast, postnatal-onset problems in development usually result in deterioration in structure or function that has previously been normal. Deterioration may reflect postnatal accumulation of a toxic metabolic product (as in phenylketonuria), progressive storage of a metabolite (as in Hurler syndrome), deteriorating energy production (as in mitochondrial myopathies), or ongoing infection (as in deafness from cytomegalovirus). Children with postnatal problems usually appear to have thrived in utero. The structural

**FIGURE 35-1** Approach to a child with structural defects.

and functional consequences of the problem manifest after the newborn period.

Certain historical information can be particularly helpful in determining the onset of the problem. Structural defects of prenatal onset are frequently associated with the following abnormalities noted by the mother during pregnancy and at the time of delivery, whereas, by contrast, with postnatal-onset structural defects, the pregnancy and delivery usually are normal.

Alterations of pregnancy associated with prenatal onset of developmental problems are as follows:

1. Alterations in gestational timing (prematurity or postmaturity). As discussed in several other chapters, the majority of conceptuses do not survive to be born at 40 weeks gestation. Much of this loss occurs in the very early part of pregnancy and is the result of gross chromosomal abnormalities and/or malformation. Numerous studies have documented an increased frequency of chromosomal and genetic abnormalities in losses from the second and third trimesters. Thus, premature delivery may reflect late fetal wastage rather than maternal disease. Postmaturity rarely occurs today because of improved fetal monitoring techniques. In years before the widespread use of the ultrasound, anencephaly typically presented in pregnancies that continued well beyond the due date since the fetal pituitary–adrenal axis is involved in the triggering of labor.
2. Alterations in the onset of fetal activity, nature of fetal activity, or both. Although it is clear that fetal activity begins much earlier, it is usually not felt by the mother until about 18 weeks of gestation. Fetal activity increases in amount and intensity from that time, reaches a maximum between 29 and 38 weeks,

and then decreases somewhat until delivery. Discussion with mothers who have given birth to babies with structural defects suggests that certain structural defects are often associated with delayed onset and/or decreased intensity of fetal activity. Moreover, fetal movement may be localized to one particular quadrant of the abdomen, for example, when the defect represents deformation due to intrauterine compression in a previously normally formed structure. Other examples are defects in brain development and meningomyelocele, conditions in which the decreased fetal activity is secondary to neurologic impairment.

3. Abnormalities in the amount of amniotic fluid, for example, polyhydramnios or oligohydramnios. During the latter part of gestation, amniotic fluid is maintained in equilibrium by fetal urination and fetal swallowing. Polyhydramnios occurs when the fetus has difficulty swallowing amniotic fluid, for example, because of early problems in central nervous system development or upper gastrointestinal obstruction. Oligohydramnios is usually present after chronic leakage of amniotic fluid or whenever fetal urinary excretion is decreased, for example, because of renal agenesis, infantile polycystic kidney disease, or urethral obstruction.

Alterations noted at delivery associated with prenatal onset of developmental problems are as follows:

1. Increased incidence of breech presentation. Breech presentation occurs in 3.1 percent of normal deliveries at 40 weeks gestation. However, it occurs much more frequently in some disorders that adversely affect the form and/or function of the fetus. Defects of form include structural abnormalities such as hydrocephalus, which would be less compatible with the

vertex position because of the large head and joint dislocations, which may limit the capacity of the fetus to alter its position. Defects of function include some conditions associated with neuromuscular dysfunction, for example, the trisomy 18 syndrome and Smith–Lemli–Opitz syndrome associated with hypertonemia and the Prader–Willi syndrome and Zellweger syndrome associated with hypotonia.

2. Prenatal-onset growth deficiency. Drillen (7) studied the incidence of malformations, mental retardation, and/or neurologic defects in 180 1-year-old children whose birth weight was 2000 g or less and who were small for gestational age. She documented an increased incidence of prenatal-onset malformations as weight-for-gestational age decreased. In addition, she showed a marked increase in suspected mental and neurologic defects in those small-for-gestational-age children who had some structural anomaly.
3. Difficulty with neonatal adaptation. Children with prenatal-onset structural defects frequently have problems with neonatal respiratory adaptation, probably secondary to malformations of brain structure. Therefore, one should always be cautious when attributing mental retardation to a perinatal insult in a child who has associated prenatal-onset structural malformations. Mental retardation in such patients may well be related to a problem in brain development of prenatal onset.

Other historical information that will be useful in determining etiology includes the following:

1. Family history with attention to any health, developmental, or functional issues in first-, second-, or third-degree relatives as well as the presence or absence of consanguinity;
2. Past obstetrical history with attention to unexplained fetal losses;
3. Maternal health and exposure history in mothers with diabetes, epilepsy, and certain immunological conditions may have a higher risk for adverse outcomes. Certain drugs, chemicals, and infections are known to increase risk.

The most helpful way to determine whether a structural defect is of prenatal or postnatal onset is a careful physical examination (8). In the vast majority of situations, the nature of the problem will determine the direction the diagnostic evaluation should take. The physical examination should focus on delineating the pattern of major and particularly minor malformations. Major malformations are birth defects that have significant cosmetic and/or functional consequences to the individual concerned. About 15–20% of stillborn babies and 2–3% of all live-borns have a major malformation, and an additional 2% have occult cardiac, renal, and nervous system malformations that become manifest by age 5 years. Major anomalies are often what bring an

individual to clinical attention, but they rarely lead to an etiologic diagnosis.

Minor malformations, on the other hand, have no functional or cosmetic consequences for the affected individual, and include, for example, complete two to three syndactyly of the toes or a single transverse palmar crease. By definition, minor malformations occur in less than 4% of the general population. Although these anomalies themselves have few adverse implications, the presence of two or more minor anomalies greatly increases the likelihood of a major anomaly. In addition, certain minor anomalies (such as a preauricular tag) may be associated with specific major anomalies (such as hearing loss). Moreover, most syndromes are diagnosed based on the pattern of minor malformations rather than the major malformations with which they occur. For example, a diagnosis of Down syndrome may be suspected in an infant with upslanting palpebral fissures, epicanthal folds, small ears, a flat face, loose nuchal skin, a single transverse palmar crease, and wide spaces between toes one and two regardless of the presence of a cardiac defect. Lastly, minor malformations may provide clues as to the timing of the insult in development. For example, the interphalangeal flexion creases develop at about 9 weeks gestation in response to movement across the joint. Hand contractures associated with absent palmar creases suggest that the fetal hand was not moving at 9 weeks gestation, whereas, contractures in the face of normal creases suggest that early hand movement was normal.

In addition to structure, posture, tone, and behavior may all provide diagnostic clues.

### 35.3 PRENATAL-ONSET PROBLEMS IN DEVELOPMENT

Once a given problem has been determined to be of prenatal onset, a distinction should be made between those that are single primary defects in development and those that are multiple malformation syndromes. Although the concepts are not totally analogous, separation of prenatal problems into these two categories permits some practical generalizations that can be extremely helpful in counseling about recurrence risk.

Conceptually, “single primary defect in development” is an anatomic or morphogenetic designation. In most cases, the defect involves only a single structure, and the child is otherwise completely normal. Table 35-1 sets

**TABLE 35-1 Common Single Primary Defects in Development**

Malformation: Cleft lip ± cleft palate, cleft palate, cardiac septal defects, defects in neural tube closure
Deformation: congenital hip dislocation, talipes equinovarus
Dysplasia: pyloric stenosis

forth the seven most common single primary defects in development. For most of them, the specific etiology is unknown, making definitive recurrence risk counseling difficult. However, from a practical standpoint, most single primary defects are explained on the basis of multifactorial inheritance, which is thought to carry a recurrence risk for first-degree relatives of between 2% and 5%. Thus, recognition that a child's structural defect represents a single primary defect in development usually enables the clinician to suggest recurrence risk percentages between 2% and 5% for unaffected parents with one affected child.

The multifactorial model is a theoretical construct that was developed to explain the observed 2–5% risk for first-degree relatives, the twin discordance and gender inequality observed for many common single defects. The model stipulates that expression of a given characteristic represents the interaction between genetic susceptibility to a given biologic error and a threshold beyond which a given characteristic is expressed. Susceptibility is depicted as a normal distribution in the population. The threshold may be manipulated by environmental factors, which may either increase or decrease the likelihood that a defect will be evident. The extent to which multifactorial inheritance contributes to the etiology of some of the less common single defects in development is at present unclear. The fact that single primary defects are etiologically heterogeneous implies that some will have a clearly environmental etiology, whereas others will result from dominantly or recessively inherited single altered genes. Craniosynostosis secondary to in utero constraint is an example of the former, and postaxial polydactyly illustrates the latter. Before multifactorial risk figures are used for counseling, references such as OMIM (6), or Practical Genetic Counseling (9) should be consulted to determine if other risk figures have been reported.

In contrast to the anatomic concept of the single primary defect in development, the designation “multiple malformation syndrome” indicates that the observed structural defects all have the same cause. The defects themselves usually include a number of anatomically unrelated errors in morphogenesis. Multiple malformation syndromes are caused by gross chromosomal abnormalities, chromosomal microdeletions and duplications, teratogens, and single-gene defects usually inherited in Mendelian patterns. Recurrence risk depends on an accurate diagnosis and ranges from zero in cases that represent fresh gene mutations or are caused by one-time teratogen exposures to 100% for the unusual case of a child with the Down syndrome in which one parent is a balanced 21/21 translocation carrier. To review, recognition that a child has a prenatal-onset single primary defect in development suggests a 2–5% risk; recognition that a child has a multiple malformation syndrome is not helpful with respect to recurrence risk counseling unless a specific diagnosis can be made.

### 35.3.1 Single Primary Defect in Development

Single primary defects can be subcategorized, as shown in Table 35-1, according to the nature of the error in morphogenesis that has produced the observed structural defect (10). Thus, single primary defects involve malformation, deformation, disruption, or dysplasia of the developing structure. A malformation implies a primary structural defect arising from a localized error in morphogenesis. A deformation should be thought of as an alteration, usually through compression, in shape and/or structure of a part that has differentiated normally; the term disruption is used for a structural defect resulting from destruction of a previously normally formed part. The term dysplasia refers to an abnormal organization of cells and the structural consequences. Dysplasias may be localized or generalized. Localized dysplasias (e.g. hemangiomas) are generally single primary defects in development. However, generalized dysplasias such as connective tissue disorders usually present as multiple malformation syndromes in that a variety of structures are involved because of the widespread distribution of the dysplastic tissue.

Table 35-1 sets forth the most common single primary defects in development. Four are malformations, the result of a localized error in morphogenesis. Two (congenital hip dislocation and talipes equinovarus) are the result of intrauterine molding and thus represent deformation of previously normally formed structures. One (pyloric stenosis) is a dysplasia resulting from abnormal muscular hypertrophy at the gastric outlet. Each of these seven anomalies occurs with a frequency of 0.5 to 1 per 1000 in live-born infants. The major reason for separating single defects in development into malformation, deformation, disruption, and dysplasia is to gain information that can be helpful relative to prognosis. Of the deformations noted at birth, 90% will correct spontaneously; of those that do not, the vast majority can be corrected with early postural interventions, such as casting or bracing. Conversely, spontaneous correction of both malformations and disruptions almost never occurs, and, when correction is possible, surgery is virtually always necessary. Because dysplasias involve abnormal organization and localized deregulation of growth in affected structures, many change over time with involution occurring in some and malignant transformation taking place in others.

### 35.3.2 Malformations

Most children with a localized malformation in development, such as a cardiac septal defect or cleft lip and palate, are otherwise completely normal. After appropriate reconstruction, prognosis is excellent. In those cases in which Mendelian inheritance has not been previously documented, multifactorial recurrence risk figures

(2–5%) can be given to unaffected parents. If the malformation in development involves a structure that is not amenable to surgical correction, such as the brain, the long-term prognosis may be poor. The environmental factors that modify the threshold for expression of most malformations are for the most part unknown. For neural tube malformations, however, folic acid supplementation before conception substantially reduces the risk for recurrence (11).

### 35.3.3 Deformations

Most deformations involve the musculoskeletal system and are believed to be caused by intrauterine molding (12). The pressure required to produce such molding may be intrinsic (e.g. neuromuscular imbalance within the fetus) or may be extrinsic (e.g. fetal crowding). In either case, the ability of the fetus to kick is impaired, resulting in decreased fetal movement, an important factor in the development of a normal musculoskeletal system. This is particularly true with respect to joint development because motion is essential for normal development of the joints. In addition, because of fetal plasticity, marked positional deformation of any body part can occur when the fetus is unable to change position and thus alter the direction along which potentially deforming extrinsic forces are being directed.

**35.3.3.1 Intrinsically Derived Prenatal-Onset Deformations.** Disorders involving muscle degeneration, such as Steinert myotonic dystrophy, and disorders involving motor neurons, such as Werdnig–Hoffmann disease, are uncommon causes of positional deformations. Early defects in development of the central nervous system are more common causes and should be seriously considered whenever a structural defect is thought to be an intrinsically derived prenatal-onset deformation.

**35.3.3.2 Extrinsically Derived Prenatal-Onset Deformations.** Fetal crowding, the common pathway in extrinsically derived postural deformations, is usually due to a decreased volume of amniotic fluid, a situation that occurs normally during the later weeks of gestation when the fetus undergoes extremely rapid growth. However, it also occurs abnormally when fetal urinary output is diminished and in cases of chronic leakage of amniotic fluid. Other extrinsic factors associated with the development of deformations include breech presentation and the shape of the amniotic cavity. When a fetus is held in the breech position, the legs may be trapped between the body and the uterine wall. In that position, the fetus is unable to kick optimally and therefore is immobilized and more susceptible to molding and deformation. Breech presentation is associated with a 10-fold increase in the incidence of deformations. The shape of the amniotic cavity, which has a profound influence on the shape of the fetus that lies within it, is influenced by many factors, among which are the following: uterine shape; volume of amniotic fluid; size and shape of the

fetus; presence of more than one fetus; site of placental implantation; presence of uterine tumors; shape of the abdominal cavity, which is influenced by the pelvis, sacral promontory; and neighboring abdominal organs; and tightness of the abdominal musculature.

The various forms of talipes and congenital hip dislocation are the most frequently observed congenital postural deformities. Most children with these deformations are otherwise completely normal, and their prognosis is excellent. Correction usually occurs spontaneously. However, recognition that a structural defect represents a deformation does not always imply fetal crowding and should lead to careful consideration of other etiologic possibilities that might have far greater importance to the child. For example, because decreased fetal movement can be secondary to serious neurologic abnormalities, multiple joint contractures should always alert the clinician to the possibility of a malformation in central nervous system development. Although the most common deformational single primary defects—congenital hip dislocation and talipes—have a 2–5% recurrence risk, most deformations are the result of physiologic crowding and have virtually no recurrence risk. Deformations that are due to pathologic crowding (e.g. uterine tumors or malformation) have a much higher recurrence risk unless the factors leading to crowding are altered before subsequent pregnancies. Deformations that are the result of an underlying malformation (e.g. renal agenesis) have a recurrence risk similar to that for the underlying malformation.

### 35.3.4 Disruptive Defects

Disruptive defects occur when there is destruction of a previously normally formed part. There are at least two basic mechanisms believed to produce disruption. One involves entanglement followed by renting, amputation, or both of a normally developed structure, usually a digit, arm, or leg, by strands of amnion floating within amniotic fluid (“amniotic bands”) (13).

The second mechanism through which disruption occurs involves the interruption of blood supply to a developing part, leading to infarction, necrosis, and resorption of structures distal to the insult. If interruption of blood supply occurs early in gestation, the disruptive defect seen at term usually involves atresia or absence of a particular part. If the infarction occurs later, necrosis is more likely to be present. Examples of disruptive single primary defects for which infarctive mechanisms have been implicated include nonduodenal intestinal atresia (14), gastroschisis (15), pencephaly, and transverse limb reduction defects (16). The extent to which disruption of developing structures plays a role in dysmorphogenesis is unknown (17).

Because disruptions do not involve programming errors intrinsic to the fetus, genetic factors appear to play a minor role in their pathogenesis. Thus, most disruptive

defects are sporadic events in otherwise normal families. Cocaine is an environmental agent whose mechanism of action is vascular disruption. Multiple disruptive defects have been seen in the offspring of women who abuse this agent in pregnancy (18). The prognosis for a disruptive defect is determined entirely by the extent and location of the tissue loss. Thus, a child with a limb amputation has an excellent prognosis for normal function but a child with porencephaly does not.

### 35.3.5 Dysplasia

The causes of the vast majority of localized dysplasias are unknown. Because many generalized dysplasias are the result of abnormal genes, it is probable that localized dysplasias will reflect somatic mutation in specific tissues. This hypothesis is consistent with the observation that empirical recurrence risks for localized dysplasias are low. The process of dysplasia appears to involve deregulation of growth; hence most dysplasias change over time. Capillary hemangiomas become involuted (the bathing trunk nevus illustrated in Figure 35-5 carries a risk for malignant transformation). Knowledge of the natural history of a lesion is critical in the long-term follow-up of children with localized dysplasias.

### 35.3.6 Sequence

“Sequence” describes the pattern of multiple anomalies that occurs when a single primary defect in early morphogenesis produces multiple abnormalities through a cascading process of secondary and tertiary errors in morphogenesis. When evaluating a child with multiple anomalies, it is extremely important from the standpoint of recurrence risk counseling to differentiate between multiple anomalies secondary to a single localized error in morphogenesis (a sequence) and a multiple malformation syndrome. In a sequence, recurrence risk counseling for the multiple anomalies depends entirely on the recurrence risk for the initiating, localized error. The words malformation, deformation, disruption, and dysplasia sequence are used if the nature of the initiating error in morphogenesis is known.

The patient depicted in Figure 35-2 has mandibular hypoplasia, glossoptosis, and cleft palate, an example of multiple anomalies secondary to a single localized error in morphogenesis. The primary defect in this case is mandibular hypoplasia, a malformation. Because the tongue is relatively large for the oral cavity, it drops back (glossoptosis), blocking closure of the posterior palatal shelves, resulting in a U-shaped cleft palate. This condition has previously been referred to as the Pierre Robin syndrome. However, because both glossoptosis and cleft palate are secondary to mandibular hypoplasia, the disorder is now referred to as the Robin malformation sequence. Recognition that all of the observed defects are due to a single localized error in morphogenesis (mandibular

**FIGURE 35-2** Infant with the Robin malformation sequence. (A) Micrognathia. (B) U-shaped palatal cleft.

**FIGURE 35-3** Newborn infant with breech deformation sequence. Note the deformed cranial shape and positional deformities at the hips and feet.

hypoplasia) permits recurrence risk counseling based on the etiology of the single defect. The patient depicted in Figure 35-3 has bathrocephaly, torticollis, facial asymmetry, a dislocated right hip, and valgus anomalies of both feet. All of the structural defects are the result of compression of developing fetal parts. The pattern of abnormalities in this patient is referred to as the breech deformation sequence. Intrauterine crowding in this situation was the result of a large infant with a birth length of 54 cm, birth weight of 3.9 kg, and head circumference of 36 cm, delivered from a breech position to a small, primigravida mother. Recurrence risk is therefore negligible. Recognition of the deformational nature of the abnormalities is helpful with respect to prognosis. All the problems should resolve spontaneously or with postural therapy.

The patient depicted in Figure 35-4 has the amnion rupture sequence. All of the craniofacial and limb defects

**FIGURE 35-4** Infant with amniotic band disruption sequence. Note the asymmetrical encephalocele, severe disruption of facial development, and digital anomalies.

are secondary to multiple fibrous strands of amnion extending from the placental insertion of the umbilical cord to the surface of the amnion-denuded chorion or floating freely within the chorionic sac. These strands of amnion, which result from disruption of the normally formed membrane, cause secondary defects through any one or more of the following mechanisms. Malformations occur if a strand of amnion interferes with the normal sequence of embryologic development. For example, a strand of amnion could interrupt fusion of the facial processes so that a cleft lip would result. Disruptions, on the other hand, are secondary to tearing apart of structures that have previously developed normally. As such, an amniotic band might act to cleave areas in the developing craniofacies along a line not conforming to the normal planes of facial closure. Deformations due to fetal compression occur secondary to oligohydramnios, tethering of a fetal part, or both. The former situation may result from rupture of both amnion and chorion, leading to chronic leakage of amniotic fluid. Tethering occurs when the fetus or one of its parts becomes immobilized by the constraining effect of an amniotic band such that it is unable to change position and thus alters the direction along which potentially deforming forces are being directed.

When used in conjunction with the word sequence, malformation, deformation, disruption, and dysplasia describe only the initiating error in morphogenesis of the sequence. The nature of the individual secondary defects that ensue from the initiating event depend on the manner in which the initiating error alters subsequent morphogenesis. In the case of the amnion rupture sequence, the initiating event, disruption, can lead to multiple structural defects through three of the mechanisms listed earlier.

The child depicted in [Figure 35-5](#) has a neurocutaneous melanosis sequence. In this dysplasia sequence,

**FIGURE 35-5** Infant with neurocutaneous melanosis. Note the bathing trunk nevus. This infant also had seizures, presumably from melanocytic infiltration of the pia and arachnoid.

melanocytic hamartosis of the skin occurs in conjunction with similar changes in the pia and arachnoid. Affected individuals are at risk for malignant degeneration within the hamartoses and are also at risk for neurologic sequelae, including seizures and mental retardation. Although the etiology of this sporadic condition is unknown, the single defect in development is presumed to involve melanoblastic precursors migrating from the neural crest.

Finally, a sequence, like any other single defect in development, can occur by itself in an otherwise normal individual or may be one feature in a multiple malformation syndrome. Stickler syndrome, cerebrocostomandibular syndrome, and spondyloepiphyseal dysplasia congenita are examples of multiple malformation syndromes in which the Robin malformation sequence represents one feature. In this situation, recurrence risk counseling is based on the etiology of the overall condition.

### 35.3.7 Multiple Malformation Syndromes

The category of multiple malformation syndromes includes patients in whom a primary developmental anomaly of two or more systems has occurred, all of which are thought to be due to a common etiology. Other than Down syndrome, which has an incidence of 1:660, and XXY syndrome (1:500 males), few of these disorders occur more frequently than 1 in 3000 live births.

As shown in [Figure 35-1](#), multiple malformation syndromes can be categorized on the basis of etiology.

### 35.3.8 Chromosomal Abnormalities

The ability to perform chromosomal studies has led to the recognition of a number of multiple malformation syndromes due to chromosomal abnormalities. Two classic

references delineate the features of the most common of these (19,20). Certain generalizations are important to consider when deciding whether or not a chromosome study should be performed. First, because chromosomes are present in most cells of the body, a chromosome aberration may be expected to affect adversely many parts of the body. Consequently, a person with only an incurved fifth finger and a heart defect is very unlikely to have those features on the basis of a chromosome problem. Second, some sex-chromosome disorders (e.g. XXX, XXY, and XYY) have few, if any, defects recognizable at birth and may present as postnatal problems in development associated with learning difficulties and behavioral challenges. In addition, as more experience is gained with chromosomal abnormalities involving very small deletions and duplications (currently referred to as copy number abnormalities), it has become increasingly clear that prenatal growth deficiency and mental retardation should not be the only requirements for chromosome studies.

The most common disorder associated with a chromosomal abnormality is Down syndrome (trisomy 21). The principal features of the disorder (flat facies with upward slant to the palpebral fissures, hypotonicity, and small ears) are usually present at birth, making a clinical diagnosis possible in the newborn period. Ear length is measured by the maximum distance from the superior aspect to the inferior aspect of the ear. Aase and colleagues (21) documented decreased ear length as a consistent feature in newborn infants with Down syndrome. In their series, no full-term white infant with Down syndrome had an ear length greater than 3.4 cm (mean 3 cm), and no normal full-term white infant had an ear length less than 3.2 cm (mean 3.8 cm).

Until recently, the most commonly performed screening test to define the etiology of an unrecognized, prenatal-onset multiple malformation syndrome was a high-resolution chromosome analysis (>550 band resolution).

Another technique that may be useful in certain circumstances is fluorescent in situ hybridization (FISH) analysis. Because the probes used to perform FISH are specific to defined areas of the genome, FISH analysis is not a screening technique, but rather is best applied when there is high clinical suspicion of a recognized pattern of malformation for which FISH analysis is available (i.e. velocardiofacial syndrome or Williams syndrome).

Comparative genomic hybridization (CGH) and single-nucleotide polymorphism (SNP) arrays are technologies that have moved into the arena of constitutional chromosomal abnormalities. Array-based CGH identifies copy number variation (either duplication or deletion) across the entire genome at high resolution. The most broadly available arrays use fluorescence techniques to compare DNA content in two differentially labeled genomes. Thousands of individual DNA sequences can be simultaneously interrogated, providing precise

information about copy number at specific genomic locations. Several platforms are commercially available for testing. Most use oligonucleotides. In addition to detecting copy number changes, SNP arrays have the capacity to detect areas of homozygosity that could suggest unknown or undisclosed consanguinity or uniparental disomy (UPD). Arrays vary in resolution and coverage. Most currently provide <1 Mb resolution and dense coverage in areas of known clinical significance. Recent meta-analysis of the diagnostic yield of array CGH in the evaluation of individuals with learning disabilities and congenital anomalies has suggested a 10% rate of causal copy number abnormalities. The down side of the technology is that it also detects copy number abnormalities that will eventually be determined to be noncausal (usually based on parental studies) at almost the same rate, 7%, the false-positive rate (22). Some have advocated that array CGH should be a first-line diagnostic test in the evaluation of a child with a multiple malformation syndrome, given the ability of the technology to identify causal copy number changes that might not be specifically suspected on clinical grounds alone as well as all of the aneuploid anomalies identified on routine chromosome analysis and diagnostic FISH testing (23,24). Arguments against the routine use of array CGH focus primarily on cost, the false-positive rate (which adds cost if parental studies are required), and the inability of the technology to detect balanced rearrangements. If using array CGH as a first-line test, it must be borne in mind that the technology cannot detect balanced rearrangements such as translocations and inversions that may relate directly to the phenotype or represent a predisposing factor to rearrangement.

Recurrence risk counseling for chromosome abnormalities depends on the nature of the cytogenetic abnormality identified. Risk is usually low in aneuploidy; however, the risk for certain trisomies (21, 18, XXX, and XXY) may increase with increasing maternal age. In case of an unbalanced translocation, parental karyotypes are warranted before specific risks are cited. In cases of de novo abnormalities, the risk is usually low except for the rare circumstance of gonadal mosaicism in a parent. Most microdeletion and microduplication syndromes are mediated by low copy repeats and carry a low risk for recurrence.

### 35.3.9 Disorders with Known Genetic Etiology

A single mutant allele or a pair of mutant alleles has been implicated as the cause of some recognizable multiple malformation syndromes of prenatal onset. Correct diagnosis in most of these disorders depends on clinical recognition, because in the majority of cases there is no testing available for the abnormal gene, although this is changing at a very rapid rate. A family history of a similarly affected individual can be extremely helpful in

suspecting that a single gene might be operative. However, many patients with multiple malformation syndromes of genetic etiology represent simplex events as a result of fresh gene mutation or the first presentation of an autosomal recessive disorder in a family. In such situations, family history will be noncontributory, although older paternal age might suggest fresh gene mutation or parental consanguinity the effects of an autosomal recessive gene. Diagnosis of most single-gene disorders depends entirely on the evaluation of the patient's phenotype. The type of laboratory evaluation that may be helpful as an adjunct to clinical recognition is usually an extension of the physical examination, for example, radiographic assessment of bony structure or tissue histopathology. As the genetic basis for many single-gene disorders is elucidated, diagnosis by mutation analysis has become available. However, the cost for some genetic tests is still quite high. Thus, most diagnoses still rest on clinical assessment.

In addition to Mendelian patterns of inheritance, some multiple malformation syndromes may arise as a consequence of dosage imbalance of a gene. At some loci in the genome, only one copy of a gene is active even though two copies are normally present. Inactivation of one member of a gene pair involves the process of imprinting. Parent of origin effects are evident at imprinted sites where it is possible in a normal individual to document that either the maternally inherited copy of the gene or the paternally inherited copy of the gene is active. Prenatal-onset multiple malformation syndromes may occur if an abnormality in the imprinting process causes both the maternal and paternal genes to be active (or inactive) at a specific locus or if an affected individual inherits two copies of a gene from one parent and none from the other. The latter situation is termed UPD. Each of these mechanisms accounts for some cases of the Beckwith–Wiedemann syndrome. The extent to which imprinting and UPD play a role in the etiology of genetically determined multiple malformation syndromes is at present unknown.

### 35.3.10 Disorders Caused by Teratogens

Disorders caused by teratogens include multiple malformation syndromes due to the effect of specific infections and drugs or chemical agents with which the embryo or fetus has come into contact. These disorders take on special importance because they represent the only group of dysmorphic conditions in which prevention before conception may be feasible. This is particularly true in the case of drugs and chemicals if the mother is aware that the agent in question can affect her baby. It is difficult, on the other hand, for a pregnant woman to avoid contact with all infectious agents. Immunization of at-risk individuals may assist in prevention of birth defects caused by specific viral infections (e.g. rubella or varicella-zoster virus).

A careful history of drug intake and chemical exposure should be obtained from the parents of all children with multiple malformation syndromes. This is particularly true when the etiology of the disorder is unknown. Two excellent references in determining the teratogenic potential of any environmental factor with which the mother has had contact are available (25,26). In addition, several online databases are available through subscription, including Reprotox (27) and Teris (28) (which includes Shepard).

Although a specific and easily distinguishable phenotype does not exist for each of the infectious agents that are commonly associated with altered fetal development, intrauterine infection can be suspected, based on the overall pattern of malformation. Any small-for-gestational-age patient with microcephaly or hydrocephalus; ocular findings including microphthalmia, chorioretinitis, cataracts and/or glaucoma; hepatosplenomegaly; and thrombocytopenia and who is developmentally delayed may be suspected of having had an intrauterine infection. It should be emphasized that each of these intrauterine infections has a wide spectrum, from fetal death, to the severely affected newborn infant with multiple malformations, to the child with no malformation disabilities. The latter situation is illustrated by a study by Hanshaw and coworkers (29) indicating a significant increase in school failure and deafness after clinically inapparent congenital cytomegalovirus infection (another exception to the prenatal–postnatal distinction set forth at the beginning of the chapter).

### 35.3.11 Recognized Patterns

Most multiple malformation syndromes are diagnosed based on the pattern of malformation in the affected individual, specifically the pattern of minor malformations. As the molecular basis for many syndromes is elucidated, etiologic heterogeneity has become the rule rather than the exception. A case in point is Rubenstein–Taybi syndrome (RTS). This disorder is a well-recognized pattern of malformation associated with pre- and postnatal growth deficiency, mental retardation, typical craniofacial features that change over time, and distinctive limb anomalies. Most cases of RTS are produced by functional loss of one copy of the gene encoding the transcriptional coactivator CREB-binding protein on chromosome 16p13.3 (30). Microdeletions of this region, first thought to be causal in the majority of cases, actually account for only 11% of affected cases and produce a more severe phenotype than point mutations in the gene, which account for the majority of cases. Moreover, mutations in a second gene, *EP300* on chromosome 22q13, also produce a similar phenotype. Thus, RTS is both a chromosomal and a single-gene disorder. RTS is typical of a growing number of recognized patterns of malformation in which different genetic mechanisms may produce the same phenotype. As a note of caution, array CGH testing

will identify the deletion cases but not those due to point mutation in the gene.

Array CGH has allowed delineation of the molecular basis of previously unrecognized patterns of malformation, such as the Potocki–Lupski syndrome (31). It is interesting that, in many cases, the distinguishing phenotype has not been delineated until after the molecular cause was known.

The molecular basis of many multiple malformation syndromes remains unknown, although most will likely be determined to be a consequence of altered copy number, single-gene mutation, epigenetic factors that alter expression or function of existing genes, or as yet unrecognized environmental exposure.

## 35.4 POSTNATAL-ONSET PROBLEMS IN DEVELOPMENT

Most children with postnatal-onset malformation problems are normal at birth, having appeared to thrive in utero. Neurologic problems frequently begin within the first week of life, and deterioration is often rapid. A specific pattern of malformation is typically not present at birth; structural abnormalities develop as the result of neurologic deterioration, storage of metabolites, or progressive loss of function in a specific tissue. In disorders with a known metabolic aberration, other manifestations of the metabolic defect such as cataracts, sparse hair, coarse facies, unusual skin pigmentation, and hepatosplenomegaly are frequently present. As set forth in Figure 35-1, these disorders can be categorized on the basis of etiology.

### 35.4.1 Genetic Factors

**35.4.1.1 Metabolic Conditions.** Most metabolic conditions are the result of deficiency of a specific enzyme, transporter, or cofactor. Because of the possibility that early institution of dietary or enzyme replacement therapy may help to prevent mental retardation, these disorders are of particular interest, and newborn screening is offered for an expanding list of these conditions throughout the United States. Because the placenta is able to compensate for the metabolic deficiency, affected infants are typically normal at birth (e.g. aminoacidurias and organic acidurias). Most of these conditions have an autosomal recessive mode of inheritance. Their incidence is extremely low. Phenylketonuria (1:14,000) is the most common and represented, in its untreated state, about 1% of most institutionalized populations surveyed before newborn screening programs were instituted. A second group of metabolic conditions produces a phenotype through abnormal accumulation or storage of material in various tissues in the body. Although the placenta does not compensate for the enzymatic deficiency, the phenotype does not manifest until a

period of time has passed during which accumulation of metabolites occurs (e.g. glycogen storage diseases and mucopolysaccharidoses). Consequently, there is usually a postnatal presentation.

**35.4.1.2 Central Nervous System Degenerative States.** A genetic etiology is increasingly known for many of these disorders. However, at present, the clinical diagnosis relies on imaging and histopathology.

**35.4.1.3 Myopathies and Connective Tissue Disorders.** Myopathies and connective tissue disorders represent a group of conditions in which structures deteriorate with wear and tear over time—hence the typically postnatal presentation. A diagnosis may be suspected by the communality of the involved tissue (i.e. wound-healing problems and ligamentous laxity for connective tissue disorders or cardiomyopathy and weakness for muscle disorders).

### 35.4.2 Environmental Factors

Trauma, infection, hypoxia, and metabolic derangements can result in severe neurologic impairment. Progressive joint immobility, abnormal positioning, and paralysis secondary to central nervous system deterioration are the most frequent structural anomalies resulting from this type of injury. Deafness and cataract may also be seen.

## 35.5 CONCLUSION

A clinical approach to children with structural defects has been set forth. It is based on the concept that the diagnostic evaluation should be directed by the nature of the structural defects. The ultimate goal of this approach is a specific overall diagnosis. The purpose of a diagnosis is to address the two questions facing all parents when a child with a birth defect is born: what does this condition mean to my child and what are my chances of having another child with a similar problem? An accurate overall diagnosis is critical to understanding the natural history of the disorder such that associated complications may be anticipated through screening, appropriate interventions offered, and precise reproductive counseling be provided. The birth of a child with congenital anomalies usually places severe stress on a family eliciting all the stages of a grief response. Understanding the cause and implications of the condition is often helpful in mitigating this stress. When an overall diagnosis is lacking, a better understanding of the nature and onset of the problem is commonly possible. That in itself can often be helpful to parents and to all others dealing with children who have structural defects. Lastly, reaching an overall diagnosis may take time as some characteristic developmental and behavioral findings may not manifest until an individual is older. Reevaluation is a critical component of this approach.

### 36.1 INTRODUCTION

#### 36.1.1 Historical Overview

Pregnant patients who are undergoing genetic evaluation or prenatal diagnosis often have concerns about the possible adverse effects of nongenetic factors, such as exposures to drugs or occupational agents. Less than one-third of families seen in most genetics clinics have conditions that are principally genetic in origin, and the differential diagnosis often includes disorders that have a predominant nongenetic cause. Accordingly, it is incumbent on practitioners of clinical genetics to be aware of the non-heritable sources of human variability, their potential interactions with genetic factors, and their implications for human health, growth, and development. Teratology is the branch of medical science devoted to the study of the causes of abnormal prenatal growth and development, and this chapter focuses on the nongenetic causes. Teratological effects include structural congenital anomalies, growth disturbances, and functional deficits such as behavioral and cognitive abnormalities that may not be apparent until some time after birth.

The term “teratogen” has been used to denote an agent that can cause abnormalities of form, function, or both in an exposed embryo or fetus, but this usage is somewhat misleading. It implies that any given agent either is or is not teratogenic and that clinical teratology consists merely of memorizing a list of “human teratogens.” In reality, teratogenicity is a property of an *exposure*, which involves not only the physical and chemical nature of the agent but also the dose, route, and gestational timing involved. The occurrence of other concurrent exposures as well as the biological susceptibility of the mother and embryo or fetus are also factors that can determine whether a given exposure produces damage in a particular instance.

Although interest in teratogenic effects has been recorded in surviving fragments of tablets from ancient

Middle Eastern cultures, much of the information available in this field before 1950 can hardly be classified as more than folklore (1). Despite the pioneering experimental teratology studies of Warkany and Nelson (1940) and others, the rekindling of serious scientific and medical interest in the teratology of chemical and other exposures resulted from the successive tragedies produced by the thalidomide treatment of pregnant women and the rubella pandemics in the early 1960s.

Succeeding decades have seen significant growth of basic, clinical, and epidemiologic investigations into problems of teratogenesis. Regulatory agencies have erected barriers against the introduction of teratogenic exposures into our environment. Furthermore, the past three decades have seen the development of teratogen information services (2,3). These services, supported by computer-based information resources such as *TERIS* (<http://depts.washington.edu/~terisweb/teris/index.html>) and *REPROTOX* (<http://www.reprottox.org>), have improved the access of pregnant women and their health care providers to available information and have fostered a systematic approach to risk assessment and risk management. Unfortunately, significant public health barriers remain, and our goal of primary prevention through the avoidance of hazardous prenatal exposures remains substantially unrealized. Although progress is being made in our understanding of normal and abnormal embryonic development, the mechanisms by which most teratogenic exposures produce their pathogenic effects are still unknown.

#### 36.1.2 Mechanisms of Teratogenesis

James Wilson summarized our understanding of the biological basis of teratogenesis in the magisterial four-volume *Handbook of Teratology* he published with Clarke Fraser in 1977 (4) in terms that are still

remarkably insightful (5). Wilson formulated six principles of teratology, the third of which is, “Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.” Wilson used the term “mechanisms” in a very precise manner to mean the earliest, if not the first, event in the pathogenic pathway between a teratogenic exposure and its effect. He explained that later events in the pathogenic process might be expressed as one or more higher-level effects, such as excessive or reduced cell death, abnormal cellular interactions, reduced biosynthesis of important products, aberrant morphogenic movement, or mechanical disruption of tissues, and that these, in turn, might result in a few final common pathways of abnormal development. He explicitly recognized that little was then known about the earliest teratogenic mechanisms, which were difficult or impossible to study experimentally with the techniques available at that time (4).

Table 36-1 lists some of the mechanisms that we now know to be important in mammalian embryonic development. Of these, epigenetic control of gene expression has been very intensively studied in recent years (6–9). Epigenetic mechanisms provide a possible link between the complex genetic program that underlies early development and teratogenic exposures (see Chapter 6). For the various mutagenic mechanisms listed in the table, it is important to point out that teratogenesis and mutagenesis are not the same thing (10). Many teratogenic exposures, including those involving retinoids and thalidomide, are not mutagenic, and many chemicals that have mutagenic potential do not appear to be teratogenic when administered to pregnant women in therapeutic doses.

### 36.1.3 Genetic Susceptibility to Teratogenic Effects

It is no surprise that genetic factors influence susceptibility to teratogenic effects, given that maternal absorption, maternal and fetal metabolism, and maternal and fetal excretion of potentially teratogenic agents, as well as embryonic development itself, are under genetic control. This has been unequivocally demonstrated in experimental animals, although the direct evidence in humans is more limited (11). Nevertheless, clinical observers have repeatedly shown that the risk for recurrence of a teratogenic syndrome (assuming the exposure continues) is much higher in the subsequent children of a woman who has had one affected child than the risk of occurrence in exposed pregnancies in general (12,13).

Genetic susceptibility to teratogenic effects has also been assessed through case-control studies of common complex congenital anomalies that focus on gene–environment interactions. This approach has been used extensively for orofacial clefts in relationship to candidate genes such as *TGFA* and *NOS3* and maternal cigarette smoking and for neural tube defects in relationship to candidate genes such as *MTHFR* and *MTRR* involved in folic acid metabolism (11,14). Although statistically significant gene–environment interactions have been demonstrated in some of these studies, no such association has been found in others.

While there is no clear consensus regarding the relative contributions of genetic and environmental factors to these particular congenital anomalies or, indeed, to the total load of birth defects in general, it is clear that genetic factors by themselves do not account for many such abnormalities. With this realization has come a renewed emphasis on the prevention of teratogenic exposures. A few generalizations have emerged that help us to characterize and recognize teratogenic exposures.

### 36.1.4 Characterization of Teratogenic Exposures

Teratogenic exposures act by a relatively limited number of pathogenetic processes (5,15) that may produce cellular death, alter tissue growth (hyperplasia, hypoplasia, or asynchronous growth), or interfere with cellular differentiation or other basic morphogenetic processes, including mechanical ones. Some agents may also act by destroying (“disrupting”) normally developing structures.

Similar general effects may be produced by different teratogenic exposures. For instance, many exposures may stunt growth, resulting in a neonate who is small for gestational age. Thus, certain characteristics are common to a wide range of teratogenic exposures and may be used as general indicators of potential teratogenicity. Indicators of the fact that a teratogenic effect may have occurred include:

1. Infertility or fetal wastage
2. Prenatal-onset growth deficiency

3. Alterations of morphogenesis, i.e. congenital anomalies
4. Alterations of central nervous system function.

Exposures that have been reproducibly associated with one or more of these effects should be considered possibly teratogenic. Fetal wastage and prenatal-onset growth deficiency seem to be especially frequent indicators of teratogenicity.

These general indicators of teratogenic activity reflect disturbances of basic processes occurring in many tissues. Such processes affect critical events in growing cells and developing organisms and commonly manifest in more than one tissue or organ in the developing embryo or fetus at any one time. It is not surprising, therefore, to find that teratogenic exposures usually have the capability of producing abnormalities in more than one tissue or organ system and that teratogenic exposures tend to produce characteristic patterns of abnormal growth and morphogenesis. For this reason, while individual abnormalities of morphogenesis are not specific for a particular teratogenic exposure, certain patterns of abnormal growth and development may be distinctive.

Agents are teratogenic only under certain conditions of exposure. This is why classifying some agents as “teratogens” and others as “nonteratogens” is misleading (16). One critical factor is the developmental stage of the embryo at the time of exposure. The most sensitive period to alter embryonic development appears to be from roughly two weeks after conception to the eighth week after conception for most teratogenic exposures. Data from animal experiments suggest that earlier adverse exposures are usually either lethal to the embryo or produce no demonstrable effect on morphogenesis. Exposures occurring after the period of embryogenesis may produce problems of cell depletion or organ function and could, therefore, be related to such effects as growth retardation or renal failure. Agents that lead to fetal constraint and consequent deformations are likely to have their most significant effect in the third trimester of pregnancy, during the phase of most rapid fetal growth. Exposures to infectious agents that produce cell death or tissue necrosis may cause disruption at any stage of gestation.

Thalidomide and angiotensin-converting enzyme (ACE) inhibitors provide especially vivid illustrations of the importance of timing to teratogenesis. The pattern of limb reduction defects, facial hemangioma, microtia, ocular abnormalities, renal malformations, and congenital heart disease that characterizes the thalidomide embryopathy only occurs in children whose mothers are treated between 27 and 40 days of gestation (17). In contrast, maternal treatment with the ACE inhibitors captopril and enalapril only produces fetal renal failure and oligohydramnios during the later stages of pregnancy (18). These effects appear to result from the exquisite sensitivity of the fetus to the pharmacological

hypotensive action of ACE inhibitors during the second and third trimesters of gestation (19).

Dose is a critical feature of any teratogenic exposure. Teratogenic effects occur only when the dose exceeds a certain threshold (20). Agents that are generally considered to be safe may have adverse effects on the embryo or fetus if given in doses high enough to produce maternal toxicity. This is an especially important consideration in exposures associated with suicide attempts, drugs of abuse (e.g. toluene inhalation), or agents encountered occupationally. Chronic exposure is usually of more concern than a single exposure, given similar doses.

The route of exposure is also of importance—there is unlikely to be a risk associated with any agent when the exposure occurs by a route that does not permit systemic absorption. This is the case with many dermal exposures. Exposure to methylene blue illustrates the importance of route of exposure to teratogenicity. Several studies have found a strong association between the occurrence of intestinal atresia and the instillation of methylene blue into the amniotic sac during midtrimester genetic amniocentesis in twin pregnancies (21). The risk of intestinal atresia in an infant born after this procedure is about 20% (22). Neither oral nor topical administration of methylene blue to the mother has been associated with a similar teratogenic risk.

Some agents, such as ionizing radiation, have direct access to the embryo, whereas others do not reach the embryo until after extensive metabolism by the mother. The teratogenicity of agents that are metabolized by the mother may depend on whether the teratogenic metabolites reach the embryo or fetus in sufficient quantities to produce adverse effects. This, in turn, depends on a number of factors including the route of entry, physical properties of the agent, maternal dose, amount of systemic absorption, and maternal metabolic capacity.

Another factor that influences teratogenicity is the chemical and/or physical nature of the agent itself. Some agents are inherently more risky than others. Maternal thalidomide treatment during embryogenesis is the classic example of an exposure that usually presents little direct risk to the mother but has strong developmental toxicity. There are only a few other examples of exposures that exhibit such selective developmental toxicity.

The teratogenicity of an exposure is also influenced by both the maternal and fetal genotypes, which may result in differences in cell sensitivity, placental transport, metabolism, receptor binding, and distribution. These differences explain why only some of the children of women who have exposures that are similar with respect to agent, dose, and gestational timing exhibit adverse effects. The importance of the genetic susceptibility of the fetus to teratogenesis is clearly illustrated by the higher rate of concordance for fetal alcohol syndrome among monozygotic twins than dizygotic twins of mothers who heavily abuse alcohol during pregnancy (23).

Together, these factors probably account for most variation encountered among patients adversely affected by prenatal exposures. It must be recognized that the teratogenic potential of an exposure is commonly expressed over a wide spectrum when all exposed individuals are considered. That is to say, when dealing with affected individuals, variability of effect is the rule, not the exception.

These generalizations lead to the following conclusions:

1. Teratogenic exposures are most easily recognized (that is, the effects are most specific) at the severe end of the spectrum where a clear-cut pattern of abnormalities of growth and development often emerges.
2. As such patterns are clear only at the severe end of the spectrum, “milder” or partial effects, including single major abnormalities of morphogenesis, may be more frequent among exposed individuals and less specific to individual teratogenic exposures. Such effects may sometimes be viewed as being “consistent with a prenatal teratogenic exposure” even though they are not specific.
3. Certain general features of teratogenic exposures may be sought in screening for potentially hazardous agents, and the use of agents displaying some of these characteristics would be most prudently avoided during pregnancy.
4. All the above features should be taken into account for complete clinical characterization of the effects of a teratogenic exposure and in order to interpret this information to patients in a meaningful way. A checklist of the types of information needed for the clinical characterization of a teratogenic exposure is presented in Table 36-2. Table 36-3 presents a list of features used to characterize effects that may occur in the child as a result of such exposures. Much more information on each of these points is needed for virtually every known or suspected teratogenic exposure in humans.

### 36.1.5 Risk Assessment and Counseling for Teratogenic Effects

**36.1.5.1 Clinical Settings.** Clinical geneticists and genetic counselors need to consider the possibility of teratogenic effects in three clinical settings. The first is during the evaluation of a patient, usually a child, in whom the medical history and/or physical findings suggest the possibility of a teratogenic effect. Both a high index of suspicion and considerable skepticism are required in such cases. Careful review of the prenatal history for the nature and circumstances of any potentially teratogenic exposure is essential, and the child should be examined for major and minor abnormalities known to be associated with such exposures. Except in the case of some infectious agents, laboratory confirmation of the diagnosis is not possible and recognition of a teratogenic cause may

Utility

require the skills of an expert dysmorphologist (24–26). In many instances, a firm diagnosis can only be made by exclusion of alternative explanations for any abnormality identified and by long-term follow-up of the patient.

Concern is often voiced that informing a couple that a child’s birth defects have resulted from the adverse effects of a drug or other potential teratogenic exposure may create serious psychological problems, particularly

in situations that involve maternal drug abuse or excessive consumption of ethanol. However, only through such a frank approach will there be an opportunity to provide optimal care for the affected child and the potential for prevention of similar problems in future children. It is clear, however, that the sharing of such information may indeed produce psychological problems. Under these circumstances, long-term support for affected families through community and health care agencies is extremely important.

A second setting in which the geneticist or genetic counselor must consider a teratogenic effect is when a patient who is not currently pregnant but wishes to have children is concerned about possible teratogenic effects of a current or future medical treatment or occupational exposure. The most certain way to prevent birth defects from teratogenic exposures is exclusion of the exposure from the prenatal environment. The approach in this instance involves determining whether the exposure is of concern and, if so, whether it can be avoided, replaced by a safer alternative, completed before pregnancy, or deferred until the pregnancy is over. Although this is not always possible, increased attention should be paid by physicians to patient education to help avoid unnecessary exposures to potentially teratogenic agents during pregnancy, particularly during critical periods of embryonic or fetal development. When a woman of reproductive age requires drug therapy, the prescribing physician's discussion of risks and benefits should include the potential for teratogenic risks. Failure to inform a woman of reproductive age of teratogenic hazards relating to medical treatment or procedures may place the physician in legal jeopardy.

Sometimes it is impossible or unwise for a woman to avoid a potentially teratogenic exposure, e.g. when failure to use a potentially teratogenic treatment poses a greater risk to the woman than the treatment does, even if she is pregnant. When it is not possible or prudent to avoid such treatment, it may still be possible to minimize the magnitude of the exposure or to avoid it during the most sensitive period of embryonic development. In the final analysis, decisions regarding the use of potentially teratogenic treatments during pregnancy are best left to an informed couple, supported through a comprehensive pregnancy risk assessment, risk communication, and management process by a sensitive and knowledgeable physician or counselor.

A third circumstance in which a geneticist or genetic counselor must consider a teratogenic effect is when a patient is concerned about the possible adverse effect of an exposure during her current pregnancy. For example, half of all pregnancies in the United States are unintended, and a woman may have abused alcohol or "recreational drugs" before she realized that she was pregnant. Alternatively, she may have become pregnant while taking a particular medication that she has now stopped. In these instances, any benefit of the exposure is no longer relevant and her concern may be whether

she should terminate the pregnancy, consider prenatal diagnosis, or accept the additional risk (if any) and continue the pregnancy. Providing appropriate teratogen risk counseling in such situations requires careful evaluation of the woman, her fetus, and the exposure, as well as a review of relevant scientific literature regarding the risk and nature of potential adverse outcomes, their ability to be diagnosed prenatally, and the effectiveness with which they can be treated if they do occur.

**36.1.5.2 What Is Risk?** Three kinds of risk are used in the medical literature to describe a teratogenic effect: absolute risk, relative risk (or odds ratio), and population attributable risk. *Absolute risk* is the chance that a woman who has had a particular exposure during pregnancy will have an affected baby. Absolute risk is useful in counseling because it answers the question that most pregnant women ask about an exposure: "What is the risk of birth defects in my baby?" In addition, absolute risk can be compared directly to other familiar risks such as the risk of miscarriage following prenatal diagnosis or the risk of nontreatment of the mother's disease.

*Relative risk* is a statement of how much more likely a woman who has had a particular exposure during pregnancy is to have an affected baby than a woman who has not had that exposure. Relative risks (or odds ratios, which are numerically equivalent for uncommon events) are usually reported in epidemiologic studies of birth defects because they are easy to calculate and easy to interpret. In counseling, it often is helpful to convert a relative risk (or odds ratio) to an absolute risk, but this requires knowledge of the incidence of the birth defect(s) of interest in the population that was studied.

Population attributable risk is the proportion of adverse outcomes of a given type in the population as a whole that are caused by a particular treatment during pregnancy. Population attributable risk is generally not relevant for counseling an individual patient, but it is useful for public health officials as an estimate of the amount by which the overall rate of a birth defect could be reduced by prevention of the teratogenic exposure.

The term "high risk" may mean two different things to patients. A teratogenic risk may be considered to be high if the severity of the effect is great, e.g. a severe brain anomaly. Thus, the risk for Ebstein anomaly, a severe congenital heart defect associated with maternal lithium treatment during pregnancy, may be considered to be great, even though the frequency of this malformation among the children of women treated with lithium during pregnancy is small (27–29). Alternatively, a risk may be considered to be great if it is numerically large, even if the severity is mild. For example, maternal tetracycline treatment very frequently causes staining of the primary dentition in fetuses exposed during the second or third trimester of gestation, but this staining is only of cosmetic significance (30). Maternal treatment with thalidomide or isotretinoin during critical times of pregnancy are examples of teratogenic risks that are great in both severity and

frequency, but fortunately not many other teratogenic exposures of this kind are known to exist in humans.

**36.1.5.3 Teratogen Risk Counseling.** Providing teratogen risk counseling involves more than just identifying and estimating the magnitude of risk. The information must be communicated to the patient in a way that allows her to make informed decisions about the management of her pregnancy. The approach varies from patient to patient and depends on many factors, including the patient's cultural and social background, her understanding of the counselor's language, her level of general and scientific knowledge, and her commitment to the pregnancy. The uncertainty that usually exists complicates teratogen counseling and requires that information be provided as risks, which are difficult for many people to understand. Counselors need to be aware of the information and misinformation patients bring with them to the counseling session and how it affects their perception of risk (31,32). Finally, the importance most women place on having healthy children and the emotional circumstances that often surround teratogen risk counseling require that the counselor have considerable skill as well as a thorough knowledge of clinical teratology.

**36.1.5.4 Dealing with Uncertainty.** One of the most difficult aspects of counseling pregnant women about teratogenic risks associated with various exposures during pregnancy is the fact that there are very few exposures for which the available information is sufficient to estimate the magnitude and severity of risk with any confidence. Available data are insufficient to determine the teratogenic risk associated with conventional treatment of pregnant women with most prescription medications (33,34), and the same is true for treatment with many over-the-counter drugs or herbal remedies and occupational or environmental exposures. Nevertheless, geneticists, genetic counselors, and other health professionals who take care of pregnant women must advise them about these risks.

It is important for health professionals to admit the limitations of their knowledge to themselves and to their patients. When counseling pregnant women, risks should be presented as best estimates and couched in appropriate uncertainty. Admitting the limitations of one's knowledge in this way may be unsatisfactory for some patients and is certainly unsatisfying for the counselor, but it is better than assuming that a lack of information means a lack of risk or, alternatively, that any maternal exposure during pregnancy may pose a significant risk to the developing embryo.

## 36.2 EVALUATING THE PATIENT AND HER EXPOSURE

### 36.2.1 Evaluation of the Pregnant Patient for Teratogenic Exposures

In order to provide a context for counseling, the counselor should review the patient's general medical, obstetrical,

and family history. The purpose of teratogenic risk assessment is to determine whether a pregnant woman's exposure increases her risk of having a child with congenital anomalies above the risk that she would have if she were unexposed. The "background" risk of serious congenital anomalies usually quoted is 3–5% for the general population, but the risk for a particular woman may be much greater because of her age, family history, medical condition, or other exposures. It is common for the risk of congenital anomalies associated with these other factors to equal or exceed the risk associated with a particular exposure of concern to the patient, and it is important for any teratogenic risk to be presented in the context of these other risks for adverse pregnancy outcomes when they are present.

The dose, route, duration, and timing for each exposure of concern should be determined as precisely as possible. For example, one can usually obtain the name, amount, frequency, and length of time that a medication was taken. This is much more informative than just knowing what was prescribed. In some cases, blood levels of a drug or occupational chemical to which the patient was exposed can be used to define the exposure very precisely. In other instances, measurements of a chemical or its metabolite in the urine or an occupational hygiene assessment can help to quantify an exposure of particular concern. One should always establish the reason for the exposure (e.g. medical treatment of a particular disease) and whether the woman experienced any toxic effects herself as a result of the exposure. If toxic effects did occur, they should be described as fully as possible. The evaluation should also include information about any relevant occupational exposures and the patient's use of other medications, alcohol, tobacco, and other "recreational" drugs.

### 36.2.2 Assessing the Scientific Literature

Clinical assessment of human teratogenic risk requires the careful interpretation of data obtained from several kinds of studies (35). Fortunately, the problem of collecting and analyzing the available data has been greatly simplified by the advent of online clinical teratology knowledgebases (<http://www.reprotox.org/>; <http://depts.washington.edu/terisweb/teris/>). In some places, health professionals and patients can also obtain information on teratogenic risks over the telephone from dedicated teratogen information services (36,37).

**36.2.2.1 Animal Studies.** For many exposures, the only data available on the effects of exposure during pregnancy are the results of studies done in laboratory animals. Such studies are valuable because they provide a means of identifying exposures with teratogenic potential before humans have been harmed. Unfortunately, however, it is usually impossible to extrapolate findings directly from animal experiments to a clinical situation involving an individual pregnant woman. Comparisons

between species are confounded by differences in placentation, pharmacodynamics, embryonic development, and other factors that may influence the likelihood of teratogenic effects. In addition, the consistent response seen in a controlled experiment in a genetically inbred strain of laboratory animals often contrasts with the highly variable response seen in the outbred human population, and the doses and routes of exposure used in animal teratology experiments often are not comparable to those that usually occur in humans.

**36.2.2.2 Case Reports.** Anecdotal descriptions of individual cases in which a child with birth defects was born to a mother who was exposed to a particular drug, other chemical, or physical agent during pregnancy are often reported in the medical literature. These associations are usually coincidental rather than causal because both birth defects and maternal exposures during pregnancy are relatively frequent. Case reports may be useful for suggesting particular outcomes that require further investigation and for raising causal hypotheses, but other kinds of studies are needed to determine whether these hypotheses are true.

**36.2.2.3 Case Series.** Teratogenic exposures typically produce qualitatively distinct patterns of congenital anomalies in affected children. Most of the exposures that are currently known to be teratogenic in humans were initially identified in clinical series on the basis of such characteristic patterns of anomalies (38). The evidence of a causal relationship can be compelling when a highly characteristic pattern of congenital anomalies is recognized in children whose mothers experienced similar well-defined exposures at similar times in pregnancy, especially if both the pattern of anomalies and the exposure are otherwise rare. Fetal alcohol syndrome provides the best known example of this (39,40), but the embryopathies associated with maternal exposure to rubella virus (41), thalidomide (17,42), and isotretinoin (43) were also first recognized by astute clinicians in case series.

Because clinical series can include a very thorough assessment of the circumstances of maternal exposure and the phenotype of each affected child, they are well suited to the recognition of such syndromes. Unfortunately, however, case series are subject to extremely biased ascertainment and multiple sources of confounding. Because they do not include controls, clinical series cannot be used to provide quantitative estimates of the strength or statistical significance of a teratogenic effect. Properly conducted epidemiological studies are needed to determine the magnitude of a teratogenic risk.

**36.2.2.4 Pregnancy Registries.** Pregnancy registries are an increasingly popular method of collecting information on outcomes among women who have taken a particular drug or group of drugs during pregnancy. These registries usually depend on voluntary identification of exposed pregnancies by the women themselves or by physicians who are treating them. Pregnancy registries are most useful if they identify women for inclusion “prospectively”, i.e. during or after the exposure

but before the outcome of the pregnancy is known, to avoid the bias toward reporting adverse outcomes that occurs when cases are voluntarily submitted following delivery. A major limitation of most pregnancy registries is the lack of an appropriate control group. Comparisons are often made to “expected” rates of congenital anomalies obtained from dedicated birth defects registries with active ascertainment and rigorous standards for diagnosis and classification, usually the Metropolitan Atlanta Congenital Defects Program (44). Such comparisons are inappropriate because data are collected in a very different way for pregnancy registries. Pregnancy registries are often also limited by the quality of available data regarding the birth defect outcomes and exposures, the diagnostic methods employed, the reliability and consistency of the outcome assessments, and the length of follow-up. These limitations can be overcome if appropriate control groups are available and if the exposure and outcome data are collected in a rigorous manner. If these conditions are met, pregnancy registries can be used to ascertain patients for high-quality-exposure cohort studies (45).

**36.2.2.5 Randomized Controlled Trials.** Randomized controlled trials are generally considered to be the optimal epidemiological approach to assessing the effects of a treatment, but they are rarely used in clinical teratology. It would be unethical to conduct a trial in humans to determine if a particular maternal treatment during pregnancy caused birth defects in the infants, so trial data on fetal outcomes is usually collected in the assessment of adverse effects of treatments for maternal conditions such as hypertension or premature labor. The treatment in these studies almost always occurs after the period of embryogenesis, so available clinical trial data provide little or no information on teratogenic risks associated with first-trimester exposure.

**36.2.2.6 Cohort Studies.** Cohort studies are used in clinical teratology research to compare the frequency of birth defects among children born to women treated with an agent during pregnancy to the frequency among children whose mothers were not so treated. There are two different ways that these studies are performed: as population-based cohorts of all newborns (or all pregnancies) and as exposure cohort studies through teratogen information services.

Population-based cohort studies can provide information on many different outcomes, including ones that do not become apparent until later in childhood, if appropriate follow-up data are available. However, population-based cohort studies must be very large to be useful for clinical teratology studies because both the exposures and the outcomes of interest are infrequent. As a consequence, population-based cohort studies are very expensive to perform, and only a few have been done to assess teratogenic risks.

Exposure cohort studies provide a more practical approach because data only need to be collected on the outcomes of pregnancies in women who were exposed

to a particular agent and the outcomes of appropriate control pregnancies. Women with the exposures of interest often call a teratogen information service for counseling, so subjects can be ascertained for exposure cohort studies in the course of regular service provision. This strength is also a limitation because studies performed through teratogen information services are not representative of the population as a whole but only of women who call these services.

Both population-based and exposure cohort studies can be used to estimate relative risk and statistical significance of associations that are observed between maternal teratogenic exposures and birth defects in the children. Either type of study may be subject to serious biases and confounding if not well designed and if the effects of covariates are not appropriately considered. Both depend greatly on the quality of the information regarding exposures as well as on the quality of the outcome data. Insufficient statistical power is frequently a concern with cohort studies, especially if the exposures, the outcomes being assessed, or both are rare.

**36.2.2.7 Case-Control Studies.** Case-control studies are used in clinical teratology research to compare the frequency of a maternal exposure, such as treatment with a particular drug, during pregnancy among children with or without birth defects. Case-control studies are often population based, an important factor in avoiding many kinds of ascertainment bias. Because case-control studies focus on women who have given birth to a baby with birth defects, case-control studies are usually far more statistically powerful than population-based cohort studies of an equivalent size. A major limitation of case-control studies is that they only provide information regarding the outcome or outcomes selected for study, so that an association with birth defects of an unanticipated kind, such as a previously unrecognized pattern of minor anomalies, cannot be identified. In this regard, case definition and the system used to classify birth defects into the group(s) chosen for inclusion in the study may be of particular importance, and selection of a group of anomalies that are thought to have similar pathogenesis—for example, vascular disruption—may be more relevant than conventional anatomic classifications.

Case-control studies can be used to estimate the odds ratio and statistical significance of an association observed between birth defects in children and maternal teratogenic exposures. Like cohort studies, case-control studies depend on the quality of both the outcome data (e.g. case ascertainment) and the exposure data (e.g. exposure characterization and timing) and may be subject to serious biases and confounding. Another frequent concern with large population-based case-control studies is that many case groups involving different kinds of birth defects may be analyzed for associations with several different maternal exposures simultaneously, creating a “multiple comparisons” problem that may not be resolvable without additional investigations.

Sample size and consequent statistical power are, of course, important considerations in any epidemiological study, but the very high power of the case-control design when used with birth defect groups that are rare in the general population may raise a different issue: identification of a statistically significant risk that is real but clinically irrelevant, or nearly so. An exposure that doubles the risk of, say, sphenomelia to 2 of 100,000 from 1 of 100,000 in unexposed pregnancies but does not affect the risk of any other congenital anomaly might be of great interest in terms of pathogenesis but would be of little clinical consequence to an individual pregnant woman who seeks counseling.

**36.2.2.8 Record Linkage Studies.** Record linkage studies provide a means of performing cohort studies or case-control studies or both in a very cost-effective manner. Record linkage studies are done by connecting information on exposures during pregnancy in the mother to information on birth defect outcomes in the infant through existing electronic medical records or administrative databases. These data systems may be very large, providing excellent sample sizes. A major limitation of most record linkage studies is that the exposure and outcome data are collected for other purposes and may be of less-than-ideal quality for epidemiological research. In addition, information on important covariates is usually limited, so these factors cannot be managed in the statistical analysis.

**36.2.2.9 Ecological Studies.** Ecological studies differ from all other epidemiological studies used for clinical teratology research in that the unit of analysis is groups of people rather than individuals. Information on exposure and outcomes is collected on the group as a whole, and exposure metrics for the group, which generally includes men, nonpregnant women, and children, as well as pregnant women, are used to estimate the level of exposure during pregnancy among the mothers of children with birth defects. An advantage of ecological studies is that they can usually be performed with data that are collected for other purposes, making them much less expensive than population-based cohort or case-control studies.

Ecological studies are usually done to investigate the effects of environmental or occupational exposures to toxic chemicals or radiation. Statistical tests for association are performed between a summary measure of exposure (e.g. average concentration of a particular chemical in drinking water) and a summary measure of disease (e.g. the frequency of miscarriage) in a group. Associations observed in ecological studies must be interpreted with great caution because they are subject to the “ecological fallacy”: attributing correlations observed in groups to individual members of those groups. Because the analyses in ecological studies are performed on populations rather than individuals, consideration of confounding factors is problematic at best and often impossible.

**36.2.2.10 Data Synthesis.** Meta-analysis provides a systematic approach to identifying, evaluating, synthesizing, and combining the results of epidemiological studies. Meta-analysis is useful because it may permit quantitative conclusions to emerge from the joint assessment of several studies, which cannot be drawn from the analysis of any individual study. Meta-analysis also provides a way to assess the effects of biases and the limitations of the individual studies. However, a conclusion reached by meta-analysis is no better than the original studies on which it is based and is also subject to limitations inherent in the joint analysis. Of particular concern is combining studies that use fundamentally different definitions of exposure or outcome. Such differences are often encountered, and ignoring them may confound rather than inform interpretation of the available data.

Publication bias—the greater likelihood for studies that show an effect, especially a large effect, to be published in comparison to those that do not show a significant effect—has been found to occur in clinical teratology studies (3,46). This “file drawer problem” can be assessed in a meta-analysis if many studies are available but may not be detectable if there are only a few published studies.

An alternative way of interpreting multiple clinical teratology studies available on a particular exposure is through expert consensus. Expert consensus is a qualitative, rather than rigorously quantitative, approach that can provide a summary assessment of studies of widely varying types, sizes, and quality, including nonepidemiological studies such as clinical series. The quality and value of an expert consensus depends on the thoroughness and rigor of the assessment and, quite critically, on who is making it.

Determining whether an exposure is teratogenic in humans requires careful assessment of all relevant available information, and especially data obtained directly by study of the outcomes of human pregnancies. A statistically significant association in one or more epidemiological studies is not sufficient to establish causality without other evidence to support such a conclusion. It is critically important that observed associations make biological sense: an association between the occurrence of birth defects in a child and an exposure during pregnancy in the mother that is not biologically plausible is almost certainly not indicative of a teratogenic effect. A chemical exposure cannot be teratogenic unless it is systemically absorbed by the mother and it or its metabolic products reach susceptible sites in the embryo or placenta. Exposures that produce congenital anomalies do so only during times in which the involved structures in the embryo or fetus exhibit appropriate sensitivity. In most cases, exposure to a greater quantity of the agent can be expected to increase the likelihood of abnormalities. The existence of a reasonable pathogenic mechanism for the observed effect in animal or in vitro experiments may provide further support for a causal inference.

## 36.3 RECOGNIZED TERATOGENIC EXPOSURES

Teratogenic exposures may be conveniently grouped into four major categories on the basis of the kind of agent involved: infectious agents, physical agents, drug and chemical agents, and maternal metabolic factors. Because current information on specific agents is incomplete, in this chapter we present only general summaries for several of the more important teratogenic exposures in each group. The reader is cautioned that considerable disagreement still exists over the role of many of these exposures in the production of human birth defects. Thus, the following discussion should be used as a guide and standard clinical teratology resources and the current literature should be consulted for a more thorough consideration of any particular agent. One should not use the information included in this chapter for counseling pregnant patients regarding the teratogenic potential of particular exposures without consulting up-to-date information resources such as *TERIS* (<http://depts.washington.edu/~terisweb/teris/index.html>) or *REPROTOX* (<http://www.reprottox.org/Default.aspx>) that are designed for this purpose.

### 36.3.1 Infectious Agents

For many years, clinicians have been aware of infectious agents that can attack the fetus in utero. Recognized effects on the fetus include death, intrauterine growth retardation, congenital defects, and intellectual disability. The pathogenesis of these abnormalities can generally be ascribed to direct fetal infection, which may be associated with inflammation of fetal tissues and cellular death. Many, if not all, of these defects represent the “disruption” pathogenetic category (see Chapter 35).

Certain signs and symptoms characterize prenatal infections of the fetus and can therefore be used as indicators of a potential infectious etiology for a child’s congenital abnormalities. Direct invasion of the nervous system may result in microcephaly, often associated with cerebral calcifications, intellectual disability, disorders of movement and muscle tone (sometimes mischaracterized as “cerebral palsy,” see Chapter 37), seizures, and central auditory and visual deficits. As the eye represents a direct developmental extension of the central nervous system, it is not surprising to find such defects as chorioretinitis, cataracts, and microphthalmia. Furthermore, as the central nervous system controls limb movement, contractures and other fetal positional limb deformations are sometimes encountered in cases in which severe central nervous system damage has occurred. However, major intercalary limb reduction malformations, polydactyly, and syndactyly are not typically associated with teratogenic infections. Other general abnormalities associated with prenatal infections include prematurity, low birth weight for gestational age, and failure to thrive. Affected

infants may exhibit evidence of widespread sepsis such as pneumonitis, hepatitis with hepatosplenomegaly and jaundice, and bleeding disorders manifested by petechiae and purpura. Chronic skin rashes and certain categories of congenital heart disease, such as stenotic vascular anomalies and defects due to disturbed blood flow, may also be associated with congenital infections (47).

Ophthalmologic examination and imaging studies in the infant may reveal additional signs of congenital infection. Serological studies in the mother and infant may be helpful, but “TORCH” screening alone is usually insufficient in newborns in whom a congenital infection is suspected because not all transplacental infections are included in this test and its sensitivity and specificity are limited. Specialized serological studies, culture of the organism, PCR for the organism’s DNA, or other more specific approaches are usually necessary to diagnose a congenital infection with certainty in an affected infant (47).

#### 36.3.1.1 Viruses.

**36.3.1.1.1 Rubella.** Abnormalities associated with prenatal infection with rubella vary substantially in frequency, severity, and type according to the month of gestation in which the infection occurred (48,49). From 40–85% of infants born to women with serologically proven rubella infection during the first trimester of pregnancy exhibit associated clinical abnormalities in early infancy. The birth of severely affected children drops off rapidly with maternal rubella infection after the first trimester of pregnancy, but later-appearing manifestations, such as hearing loss, delayed intellectual development, and diabetes, may be encountered in offspring of women infected later in pregnancy.

Rubella infection of the embryo may lead to miscarriage. Infants who are born after first-trimester rubella virus infection may display a wide variety of birth defects and health problems, including intrauterine growth retardation, subsequent failure to thrive, and congenital anomalies (Figure 36-1). Ocular defects such as cataracts, pigmentary retinopathy, microphthalmia, and glaucoma are often present. Various cardiovascular anomalies, including patent ductus arteriosus, valvular and peripheral pulmonary arterial stenoses, atrial and ventricular septal defects, and possibly other vascular stenotic lesions and tetralogy of Fallot, may occur. Myocardial damage, presumably stemming from myocarditis, has also been observed. Central nervous system abnormalities may include microcephaly, intellectual disability, hypotonia, and convulsions. Signs of acute meningoencephalitis or progressive panencephalitis may occur, and sensorineural deafness or other sensory or functional disturbances are often present. Signs and symptoms of widespread systemic infection are common and may include hepatosplenomegaly, jaundice, thrombocytopenia, anemia, irregularities of ossification of the long bones, and delayed ossification of the calvarium. Affected children may also exhibit pneumonitis,

**FIGURE 36-1** A child with rubella embryopathy. Note the “blueberry muffin” petechial rash. (Photograph courtesy of Susan Reef, MD, National Congenital Rubella Syndrome Registry, Centers for Disease Control and Prevention.)

a chronic rubelliform rash, generalized adenopathy, chronic diarrhea, diabetes mellitus, or thyroid disease. A variety of immune defects, such as thymic hypoplasia and hypogammaglobulinemia, may occur, often in association with recurrent or persistent infections. It is particularly important to note that hearing and other neurologic deficits and endocrine disturbances that are not apparent in the neonatal period may develop after several months or years of age (48).

Intrauterine diagnosis of fetal rubella infection can be accomplished by immunologic or molecular methods in the second trimester of pregnancy, but these methods cannot distinguish fetuses that will have rubella embryopathy from those that will have asymptomatic infections at birth (50,51). Manifestations of rubella embryopathy such as cardiac defects or fetal growth retardation can sometimes be identified prenatally by detailed ultrasound examination.

Prevention of congenital rubella syndrome is possible through routine immunization of children with rubella vaccine (48). Although use of attenuated live rubella vaccines in pregnant women is contraindicated, inadvertent immunization of women with such vaccines early in pregnancy has not been associated with an increased risk to the fetus (52).

**36.3.1.1.2 Cytomegalovirus.** Congenital cytomegalovirus (CMV) infection has assumed a position of increasing importance in recent years as a recognized cause of perinatal morbidity and mortality. Indeed, in periods when rubella is not epidemic, cytomegalovirus may represent the most common congenital infectious cause of intellectual disability and other central nervous system disorders, including deafness (53).

Congenital CMV infection is common, but most infected infants are asymptomatic. Between 0.2% and 2.2% of newborn infants are congenitally infected with CMV, but only about 10% of these infants exhibit serious manifestations at birth (53,54). The risk of symptomatic involvement is highest in the children of women who had a primary CMV infection during the first 6 months of gestation. Previous maternal infection or the presence of antibodies in the mother's blood does not prevent fetal infection, although such antibodies appear to reduce the risk of symptomatic disease.

The classical picture of severe congenital CMV infection includes central nervous system manifestations such as microcephaly, typically associated with diffuse periventricular calcifications reflecting extensive encephalitis (53,55). Less frequently, hydrocephalus may develop secondary to obstruction of the flow of cerebrospinal fluid. These central nervous system abnormalities are associated with functional disturbances, including intellectual disability, spasticity, hypotonia, seizures, and strabismus. Ocular involvement is common with chorioretinitis, optic atrophy, microphthalmia, cataracts, retinal necrosis, calcifications, and anomalies of the anterior chamber and optic disk, all of which may produce severe visual impairment. Hepatitis with resultant hepatosplenomegaly and jaundice may occur, and bone marrow disturbances may result in thrombocytopenia, with a generalized petechial rash or hemolytic anemia. Non-CNS malformations do not appear to be unusually frequent among infants with congenital CMV infections.

Although most infants infected in utero with CMV do not display clinical symptoms in the neonatal period, 10–15% of these children develop neurodevelopmental handicaps later in life as a result of their infection. Sensorineural hearing loss is most common. Other manifestations may include intellectual disability, movement and coordination disorders, behavioral disturbances, and chorioretinitis (53,56).

Detailed ultrasound examination and fetal magnetic resonance imaging (MRI) can be used for prenatal diagnosis of fetal ventriculomegaly, cerebral calcification, and some other serious manifestations of fetal CMV infection in the second or third trimester of pregnancy (57–59), although neurological dysfunction may occur in infants with congenital CMV infection even if the prenatal imaging studies are normal. Invasive testing can be used to demonstrate fetal infection but does not distinguish symptomatic from asymptomatic involvement of the fetus. Invasive testing is most informative when there is evidence of fetal disease on ultrasound examination.

Vaccination of seronegative women may be useful in reducing the risk of fetal CMV infection associated with primary maternal infection during subsequent pregnancies (60). Treatment of pregnant women with primary CMV infections and documented amniotic fluid involvement with specific hyperimmune globulin may

reduce the frequency of symptomatic CMV disease in the children (61,62).

**36.3.1.1.3 Varicella-Zoster Virus.** Although varicella infections and zosteriform eruptions during pregnancy are relatively infrequent, a congenital varicella syndrome has been recognized since 1947 (63). The risk for the fetus to display significant teratogenic effects when the mother contracts varicella during pregnancy is small—2% or less, depending on the gestational age (64,65). The most susceptible period of pregnancy for such effects is between 13 and 20 weeks' gestation. The risk of fetal damage related to maternal zoster during pregnancy appears to be much lower than with maternal varicella (65–67).

Children infected with varicella-zoster virus in utero may display growth deficiency and microcephaly with cortical atrophy, often resulting in convulsions and intellectual disability. Other neurologic sequelae may include peripheral nerve palsies, muscle weakness, and paralysis or muscular atrophy. Secondary positional limb deformities may occur, and ocular involvement—microphthalmia, cataracts, and chorioretinitis—may be seen. Limb anomalies may include distal phalangeal hypoplasia or hypoplasia of an entire limb, possibly secondary to denervation. Cutaneous abnormalities—scars, vesicles, epidermal hypoplasia, and other bizarre craniofacial or limb anomalies, possibly secondary to in utero ulceration—may be present. Respiratory distress, pneumonitis, repeated infections, and hearing deficiency have occasionally been reported (66,68).

Some manifestations of varicella embryopathy can be detected prenatally by ultrasound or fetal MRI examination (68), but affected fetuses cannot always be identified. No reliable means has been established for prenatal diagnosis of varicella embryopathy by amniocentesis or chorionic villus sampling (CVS) (66,68).

Varicella infection of children or adults usually confers long-term immunity to chicken pox, although reactivation of a latent varicella-zoster virus infection may occur, producing zoster. Passive immunization with varicella-zoster immune globulin (VZIG) within 96 h of exposure is recommended for pregnant women who have been in close contact with someone with varicella or zoster and who are seronegative or have no history of having had chicken pox themselves (66–68). Passive immunization of a pregnant woman who has already developed clinical manifestations of chicken pox seems unlikely to prevent transmission of varicella-zoster virus to the fetus. There is no evidence that acyclovir or vancyclovir treatment of a pregnant woman who develops chicken pox affects the likelihood that she will transmit varicella virus to her fetus (67,68).

Administration of varicella vaccine after exposure to chicken pox does not prevent development of varicella and is contraindicated during pregnancy. Outcome data from a registry of pregnancies in which the mother unintentionally received live attenuated varicella virus vaccine

after conceiving show no indication of an adverse effect on the fetus (69), but the data are insufficient to rule out an effect similar in magnitude to that seen with natural maternal chicken pox during pregnancy. Secondary transmission of vaccine virus may occur.

**36.3.1.1.4 Human Immunodeficiency Virus (HIV; AIDS).** Rates of human immunodeficiency virus (HIV) transmission from mother to fetus range from 15–30% in studies from the United States and Europe in which maternal antiretroviral treatment was not given during pregnancy (70). Maternal antiretroviral treatment late in pregnancy substantially decreases the rate of vertical transmission of HIV (71–74). No evidence of a substantial teratogenic risk has been found in association with commonly prescribed antiretroviral treatments in pregnancy in a voluntary Antiviral Pregnancy Registry sponsored by pharmaceutical companies that manufacture these medications ([http://www.apregistry.com/forms/interim\\_report.pdf](http://www.apregistry.com/forms/interim_report.pdf)).

Congenital HIV infections usually follow one of two courses in untreated children (71,75,76). Most have a slow progression that resembles AIDS in adults, but 10–25% of congenitally infected infants become symptomatic in the first year of life, suffer rapid progression, and die very early. Affected infants may exhibit failure to thrive, interstitial pneumonia, recurrent bacterial and other infections, chronic diarrhea, and generalized lymphadenopathy. Growth retardation is common, and microcephaly, developmental delay, progressive encephalopathy, and other neurological abnormalities are often seen. Malformations do not appear to be unusually frequent among the children of HIV-infected women (71,77).

**36.3.1.1.5 Parvovirus B19.** Parvovirus infection causes fifth disease (erythema infectiosum) in children. Infections in adults may produce a rash or arthropathy but are often asymptomatic. Fetal infection with parvovirus B19 can cause severe anemia, hydrops, and death (78–81). Many infected fetuses that develop hydrops die, but the hydrops may spontaneously resolve. Less severely affected fetuses may have meconium peritonitis, isolated ascites, increased nuchal thickness, or pleural or pericardial effusions.

Transplacental parvovirus B19 infection occurs in 25–50% of cases of maternal primary infection during pregnancy, but in most instances, there is no apparent adverse effect on the fetus (78–80). The excess fetal loss attributable to parvovirus B19 infection during the first 20 weeks of gestation is estimated to be between 2% and 9% in various studies. The risk of fetal death is lower with maternal infection later in pregnancy.

Persistent congenital anemia has been observed in infants born after intrauterine parvovirus B19 infection (80). Myocarditis, myositis, arthrogryposis, and ocular and central nervous system anomalies have also been reported after documented intrauterine parvovirus B19 infection (78,80), but such observations are rare. In most studies, no measurable increase in the frequency of

malformations or neurological abnormalities was found among the infants of women who had parvovirus B19 infections during pregnancy (82,83).

Testing for specific IgM antibody in serum is the standard means of diagnosing parvovirus B19 infection and distinguishing primary from secondary infection in a pregnant woman (78,84,85). Prenatal diagnosis of affected fetuses is often possible by ultrasonography and detection of parvovirus B19 DNA in amniotic fluid (78,84,85). Intrauterine transfusion may be beneficial in some cases of fetal hydrops associated with parvovirus B19 infection (84,85).

**36.3.1.1.6 Other Possible Teratogenic Viral Infections.** Herpes simplex virus infections are very common, and once they occur, they are persistent and recurrent. Transplacental fetal infection with herpes simplex virus is, fortunately, rare, but the effects on the fetus can be devastating (86). They may include chorioretinitis, microcephaly, various disruptive structural lesions of the brain, growth retardation, and typical skin lesions. Disseminated infection with death in the neonatal period may occur; surviving children may be intellectually disabled. This severe herpes simplex embryopathy must be distinguished from neonatal herpes simplex infection acquired during or immediately after delivery, a much more frequent and better recognized entity (86).

Transplacental infection with lymphocytic choriomeningitis virus is an uncommon occurrence that is often asymptomatic in the mother. Fetal infection has been associated with abortion and with hydrocephalus and chorioretinitis in surviving infants (87).

Infections with West Nile virus, a mosquito-borne virus that can produce encephalitis in adults, have become common in North America. Transplacental transmission of the West Nile virus has been reported after maternal infection during pregnancy and may be associated with central nervous system disruption in the fetus (88,89).

Concerns have been raised about the possible teratogenic effects of several other viruses, including influenza virus, Epstein–Barr virus, measles virus, mumps virus, and various enteroviruses (66,87,90). Most of these viruses have been associated with miscarriage in epidemiological studies, but evidence that these agents infect the embryo or fetus and cause serious disruptive lesions is lacking or very limited and controversial. It can be anticipated that future studies will clarify these questions and identify other teratogenic viral infections.

**36.3.1.2 Bacteria.** Although a host of bacterial agents may infect the fetus antenatally, only syphilis is thought to have a significant teratogenic potential. Nevertheless, many intra-amniotic bacterial infections can have devastating fetal consequences. Furthermore, as discussed later, high sustained fever associated with such infections may itself cause damage. The clinical signs and symptoms, which could be used as indicators of a possible prenatal bacterial infection, are very similar to those for the various viral agents described previously.

Transplacental transmission of *Borrelia burgdorferi*, the spirochete that causes Lyme disease, has been documented in humans, but whether this causes miscarriage or teratogenic damage to the embryo or fetus is controversial (91–93). Maternal Lyme disease during pregnancy appears to be associated with very little, if any, increased risk of congenital anomalies in the infant, especially if the maternal illness is treated promptly with appropriate antibiotics.

**36.3.1.2.1 Syphilis.** Congenital syphilis is certainly the oldest if not the most venerable of the known prenatal teratogenic infections, having been recognized for more than 500 years. The clinical manifestations of prenatal syphilis are related to both the time of gestation in which the fetal infection occurs and the duration of the untreated infection in the mother before pregnancy (94). Although little direct information is available to confirm such a conclusion, it has been generally believed that infection of the fetus usually does not occur before the fourth month of pregnancy. The frequency of congenital syphilis in the child of a woman who has untreated primary or secondary syphilis during pregnancy is 40–50%. Many such infants are delivered prematurely, and many of the infants are stillborn or die in the perinatal period. Syphilitic infections later in pregnancy result in lower risks to the fetus, with approximately 70% of late syphilitic infections resulting in the birth of normal healthy infants and only 10% showing signs of congenital syphilis. Fetal growth retardation may occur, and a wide variety of congenital problems may result.

The manifestations in the fetus may be overlooked in the newborn infant, and structural congenital anomalies are not frequent. Signs of syphilis in the child have been grouped into those that present within the first 2 years of life (early congenital syphilis) and those that appear later. Infants with early congenital syphilis are often hydropic, have a relatively large placenta, and may display widespread evidence of hematogenous infection such as hepatosplenomegaly, jaundice, generalized lymphadenitis, anemia, thrombocytopenia, and leukemoid reactions. Rhinitis and various other cutaneous and mucosal rashes and lesions—including vesicular or bullous eruptions, maculopapular rashes that may desquamate, mucous patches, petechial lesions, edema, and condylomata lata—may occur in up to 60% of patients. Osteitis is frequent and may mimic an Erb's palsy or present as an irritable infant. Syphilitic nephrosis may appear during the second or third month of life, and other evidence of generalized infection such as bronchopneumonia, failure to thrive, or malabsorption may be encountered. Nervous system manifestations such as meningitis, cranial nerve palsies, intracerebral vascular lesions, and progressive hydrocephalus are frequent. Convulsions and hemiplegia may also occur. There may be a generalized chorioretinitis and uveitis, and optic atrophy, glaucoma, and chancres of the eyelid may be seen (94).

Later manifestations of congenital syphilis, commonly occurring beyond the age of 2 years, are also widespread. The most characteristic features are Hutchinson teeth (peg-shaped and notched permanent upper central incisors), mulberry molars, interstitial keratitis, and sensorineural deafness. Frontal bossing is also a frequent, but not specific, finding. Poor maxillary growth and saddle nose deformity are frequent craniofacial manifestations, and deep linear facial scars, particularly around body orifices (rhagades), are typical late cutaneous manifestations. Late neurological features include intellectual disability, hydrocephalus, convulsions, cranial nerve palsies, and optic atrophy (94).

Prompt treatment of mother and infant is extremely important in congenital syphilis, particularly if the infant is symptomatic. Penicillin is the drug of choice (95).

**36.3.1.3 Parasites.** Although several parasitic agents are known to cross the placenta and infect the fetus, only toxoplasmosis has been clearly shown to produce congenital anomalies. Maternal malarial infection during pregnancy has been associated with fetal growth retardation and premature delivery (96,97). Fetal infection is usually asymptomatic, although intrauterine or neonatal death may occur (96).

**36.3.1.3.1 Toxoplasmosis.** Congenital toxoplasmosis has been recognized for several decades. The major risk to the fetus arises from primary toxoplasmosis infections during pregnancy. The frequency and severity of fetal effects are strongly related to the stage of gestation in which the exposure occurs. The risk of transmission with primary maternal infection increases from about 1% around the time of conception to more than 90% near term. Most fetal infections do not cause permanent damage, but clinical manifestations of the disease are more likely and more severe with infections earlier in pregnancy. The highest risk for having a baby with severe manifestations is estimated to be 10–40% with maternal infection between 10 and 24 weeks of gestation (98–101). Many more infants, especially those whose mothers acquire *Toxoplasma* infection in the second or third trimester of pregnancy, have mild or subclinical involvement, but these infants may develop chorioretinitis or neurological abnormalities later in childhood if not treated after birth (98,99,101).

As with other prenatal infections, congenital toxoplasmosis includes a wide range of clinical manifestations (98,99,101). It is often overlooked in the newborn period because of the subtlety of its signs. Clinically apparent disease is commonly associated with central nervous system abnormalities. These may include microcephaly, hydrocephalus, intracranial calcification, intellectual disability, and seizures. In addition, chorioretinitis, microphthalmia, glaucoma, and cataracts are frequent. Other signs of generalized sepsis may occur with hepatitis, resulting in hepatomegaly and jaundice, and thrombocytopenia, resulting in anemia. Pneumonitis, diarrhea, skin rash, lymphadenopathy, and other

signs of generalized infection may be present. Even if the features are more subtle in the neonatal period, long-term follow-up has revealed a high percentage of intellectual disability, convulsions, spasticity, visual impairment, and deafness in children with serious toxoplasmosis infections. *Toxoplasma* infection during pregnancy can also cause miscarriage.

Diagnosis of primary maternal infection by *Toxoplasma* is usually based on serological studies. Prenatal diagnosis by amniocentesis can be used to demonstrate most, but not all, fetal infections in pregnant women with primary *Toxoplasma* infections (98,99,102). Ultrasound examination is useful in identifying hydrocephalus, hydrops, and other severe manifestations of fetal infection but is not a reliable means of determining whether transmission of *Toxoplasma* to the fetus has occurred. Prompt treatment of the infant is important when congenital toxoplasmosis is diagnosed at birth (98,99). Treatment of the mother is often recommended when maternal *Toxoplasma* infection is documented early in pregnancy (98–100,102). Screening of pregnant women remains controversial and is not generally recommended in North America (98,100,102). The only satisfactory preventive measure is avoidance of *Toxoplasma* infection during pregnancy by avoiding ingestion of infected foods and contact with the oocysts. Generally, this means avoiding handling or eating raw meat (especially red meat) and eggs and avoiding exposure to materials such as cat feces, which may contain the oocysts.

### 36.3.2 Physical Agents

A wide variety of physical agents are potentially teratogenic for the fetus. Among these, the most important are ionizing radiation, mechanical factors, and possibly heat. Although public concern continues, present evidence does not support any causal relationship between birth defects in humans and commonly encountered low-energy exposures to sound waves, ultrasound examination, MRI, microwaves, or computer terminals (103–106).

**36.3.2.1 Ionizing Radiation.** A considerable amount of attention has been directed to the possibility of adverse effects from high-energy radiation on fetal growth and development. In particular, episodes such as the Fukushima nuclear reactor accident have unrealistically heightened the concern over the role that high-energy radiation plays in human malformations. A careful examination of available information must address three related concerns: teratogenesis, mutagenesis, and carcinogenesis. Although most exposures to high-energy radiation during pregnancy are avoidable, some exposures in both medical facilities and in the workplace continue to occur. In some instances, valid medical indications exist for the deliberate exposure of a pregnant woman to ionizing radiation. In such cases, as with the use of any potentially teratogenic agent during pregnancy, risk/benefit comparisons must be carefully made and a decision

reached by the patient and her physician after careful discussion and consideration. When exposure of a pregnant woman to ionizing radiation is necessary, the dosage to the fetus should be minimized.

**36.3.2.1.1 Teratogenesis.** Concern over possible teratogenic effects of high-energy radiation comes both from studies with experimental animals and epidemiologic studies of the offspring of survivors of nuclear explosions at the end of World War II. These experiences suggest that very high doses of high-energy radiation (>200cGy) can produce prenatal-onset growth retardation, central nervous system damage, including microcephaly, and ocular defects (107,108). Other abnormalities produced by large doses of high-energy radiation appear to be exceedingly rare in humans, if they exist at all. Furthermore, both the rate and fractionation of the radiation dosage are extremely important considerations, as slow dosage rates or division of the dose over a period of days markedly reduces the effects of the total dosage. Thus, it would appear that under ordinary circumstances, only therapeutic levels of radiation delivered to the region of the developing embryo during the first months of pregnancy have a demonstrable risk of significant anomalies for the fetus (107,108).

Much lower doses of radiation, as might occur from gastrointestinal tract radiography, CT scanning, or other diagnostic studies are, of course, far more frequent in the population. Exposure of a pregnant woman to such low-radiation doses at any time during gestation produces an extremely low or negligible risk of malformations in the offspring (107,108). This is not to imply that radiographic exposures can be conducted with total impunity during pregnancy. Even an extremely low risk should be avoided unless there is an important benefit expected.

**36.3.2.1.2 Mutagenesis.** The mutagenic effect of high-energy radiation is well known. Present evidence suggests that there may be no threshold for this effect. Thus, even low-dose natural exposures to radiation contribute to the total population load of mutations. By the same token, radiation exposures even at diagnostic levels may have potential mutational implications for an exposed fetus (107,108). It is estimated that 1cGy of radiation to a particular gene locus in a particular cell produces a risk of mutation on the order of  $10^{-7}$ . This would suggest that a germ cell exposed to 1cGy of radiation may have on the order of 1 chance in 1000 to have undergone a mutation of some type. However, most such mutations are probably either without phenotypic effect or lethal, so the chance for fertilization of that cell to result in an individual with a genetic disorder is probably substantially less.

Ordinarily, the radiation-exposed fetus would itself not suffer from a genetic disorder produced in this manner. Rather, potential offspring of that fetus in subsequent generations might manifest the disorder. By implication then, gonadal irradiation at any time before conception may have some small risk of producing a

pathogenic mutation in the offspring. The load of such mutations presumably increases throughout a person's lifetime but in the aggregate is still very small in absolute terms under ordinary circumstances.

**36.3.2.1.3 Carcinogenesis.** Concern over the carcinogenic potential of prenatal radiation may be a slightly more realistic concern (109). However, the magnitude of this risk is again substantially lower than is ordinarily understood by the public and appears to be less than the risk associated with similar exposures in early childhood (108). Studies of leukemogenesis stemming from prenatal exposures to X-irradiation suggest that the relative risk from common low-dose exposures is no greater than 1.5 and may be substantially less. In other words, the absolute risk, at worst, may rise from 1 chance in 3000 to 1 chance in 2000 for such an exposed individual to develop leukemia.

**36.3.2.1.4 Summary.** Commonly occurring exposures of a pregnant woman to high-energy radiation through diagnostic X-ray examination or other similar low-dose exposures produce very little or no measurable risk to the child (107,108). Although such exposures should be avoided whenever possible as a matter of prudence, inadvertent exposures or exposures for valid medical indications should not be a major source of concern.

**36.3.2.2 Heat.** Possible sources of fetal hyperthermia include high fever of any cause and other factors that produce substantial elevation in the maternal body temperature, such as excessive use of a steam bath or hot tub. Studies in laboratory animals strongly suggest that hyperthermia may be teratogenic at critical stages of neural tube development (110,111). The situation is less clear for humans, but most studies are limited by poor documentation of the degree and duration of fever or other form of hyperthermia that occurred during pregnancy. In addition, fever usually accompanies serious infections, and such infections or their treatment may also have teratogenic potential in some instances. Nevertheless, an increased frequency of neural tube defects has been found in association with high fever during the period of neural tube closure in some studies (110,112). A number of anecdotal cases of neuromigrational errors, Moebius syndrome, and neurogenic arthrogryposis have also been reported in the offspring of women who had hyperthermic events during the first or second trimester of pregnancy (110). The risk associated with substantial hyperthermia during pregnancy has not been clearly defined and probably depends on the severity, duration, and gestational timing of the fever or other exposure. It would seem prudent to avoid extreme prolonged hyperthermic exposures whenever possible during pregnancy.

Serial detailed ultrasound examination is useful for prenatal diagnosis of some kinds of severe central nervous system damage following such episodes, and maternal serum  $\alpha$ -fetoprotein screening for neural tube defects is indicated if the exposure occurred between 4 and 6 weeks after the last normal menstrual period.

### 36.3.2.3 Mechanical Factors.

**36.3.2.3.1 Constraint.** Although the effects of fetal constraint on fetal growth have been recognized for many years, relatively little attention has been paid to the effects of in utero mechanical factors on fetal morphogenesis. Fetal growth or movement may be constrained by a variety of mechanical factors, including uterine malformations, large uterine myomas, oligohydramnios (whether of maternal or fetal origin), intra-amniotic fibrous bands, or multifetal gestation.

It is easy to understand how fetal constraint could result in *deformations*. Such anomalies are the result of mechanical forces that entrap and physically compress structures of the developing fetus (113). Included in this category are plagiocephaly and such positional limb deformities as clubfoot, dislocated hips, and perhaps arthrogryposis, particularly in predisposed fetuses. Such anomalies could theoretically be produced at any time during prenatal life and would seem particularly likely to occur if the degree of constraint is severe or if the fetus is predisposed because of neurologic impairment. All these fetal anomalies are etiologically heterogeneous, and similar defects may result from mechanisms other than constraint.

Recognition of factors that predispose to fetal constraint, such as uterine malformation, oligohydramnios, or multifetal gestation, should alert the physician to the possibility of adverse consequences to the fetus or the newborn. These anomalies are often effectively treated by taking advantage of the relatively normal growth potential of the "deformed" tissues through casting or other essentially mechanical forms of therapy.

By the same token, recognition of deformations in the newborn infant should alert the physician to the possibility of fetal constraint in utero. For instance, features of severe in utero compression are a common part of the so-called Potter sequence as a consequence of oligohydramnios, whether of fetal (renal hypoplasia) or non-fetal (premature rupture of the fetal membranes with amniotic fluid leakage) origin. The presence of deformations should alert the practitioner to the possibility of other disturbances of fetal growth that may commonly be associated, e.g. clubfoot and pulmonary hypoplasia with consequent respiratory distress resulting from oligohydramnios.

**36.3.2.3.2 Early Invasive Prenatal Diagnosis.** Evidence that the mechanical trauma associated with early CVS or amniocentesis may occasionally cause fetal anomalies is of particular concern to medical geneticists. CVS before 10–11 weeks' gestation, i.e. during or shortly after formation of the limbs in the embryo, has been associated with an increased risk of limb reduction defects and oromandibular-limb hypogenesis syndrome (114,115). The risk appears to be greater and the defects more severe with earlier procedures. It is unclear whether or not an increased risk for fetal limb defects exists with later CVS procedures; if so, the risk is very small

(115,116). There is also some evidence that cavernous hemangiomas, intestinal atresia, gastroschisis, and club-foot are more common than expected among children born to women who had CVS (117), but further study is needed to define these risks more clearly and to determine whether they also depend on the gestational age at which the procedure is done.

Two randomized controlled trials of early amniocentesis found a small but significantly increased frequency of talipes equinovarus among infants born to women who had undergone the procedure between 11 weeks and 12 weeks 6 days of gestation (118–120). The risk was much greater when amniotic fluid leakage occurred following early amniocentesis. Talipes equinovarus does not appear to be more frequent than expected among the children of women who undergo amniocentesis after 15 weeks' gestation.

### 36.3.3 Drug and Chemical Agents

Since the thalidomide disaster, increasing attention has been focused on the role of drug and chemical agents in the environment to which pregnant women are exposed. Unfortunately, there has been a proliferation of both therapeutic agents and environmental chemicals during the past five decades, and it has also become increasingly clear that self-medication by pregnant women using a variety of over-the-counter, herbal, and traditional medicines is a common practice. In addition, many pregnancies are unplanned, and inadvertent chemical or drug exposures are frequent. Finally, women may have medical conditions for which treatment is necessary regardless of pregnancy.

For all these reasons, health professionals who care for pregnant women often must deal with their concerns about possible teratogenic effects of drug and other chemical exposures. Far too little is known about the teratogenic potential of most drug and chemical exposures. Several major categories of agents are considered in this section: environmental chemicals, nonprescription drugs, and prescription drugs.

**36.3.3.1 Environmental Agents.** Recognition of the pollution of our environment by an ever-proliferating group of compounds has caused serious concern regarding the potential impact on the developing fetus. Relatively little is known about the teratogenic potential of many of these exposures in humans. Fortunately, however, efforts to limit exposures for the public at large and for occupationally exposed adults provide a measure of protection for the fetus as well. Nevertheless, organic mercurial compounds demonstrate the teratogenic potential that environmental exposures can have.

**36.3.3.1.1 Organic Mercury Compounds.** Ingestion by a pregnant woman of food that is heavily contaminated with methylmercury compounds can cause severe damage to the developing central nervous system of her fetus (121–123). Clusters of affected infants

have been observed after maternal consumption of methylmercury-contaminated fish in Minamata, Japan, and of grain treated with methylmercury fungicides in Iraq. The frequent outcome of such pregnancies is children with severe central nervous system damage and microcephaly, resulting in static encephalopathy that presents as “cerebral palsy.” Maternal neurotoxicity often occurs in these cases as well, but the fetus appears to be more sensitive than the adult to this effect. Malformations do not appear to be unusually frequent in affected infants.

Subtle effects on fetal central nervous system development of much lower maternal exposures to organic mercury compounds, as may occur when the mother eats large amounts of swordfish or shark, have been reported in some studies but not others (123). These studies remain controversial, but the United States Food and Drug Administration has advised pregnant women to eat fish with lower rather than relatively high mercury contents (<http://www.fda.gov/Food/FoodSafety/Product-SpecificInformation/Seafood/FoodbornePathogensContaminants/Methylmercury/ucm115662.htm>).

**36.3.3.1.2 Other Environmental Chemicals.** Women who used cooking oil that was heavily contaminated with PCBs during pregnancy had infants with intra-uterine growth retardation and a transient dark-brown staining of the skin (“cola-colored babies”) (124–126). Developmental delay was also observed in these children. Subsequent studies of infants whose mothers consumed PCBs in much smaller amounts during pregnancy have produced inconsistent findings (127,128).

Many natural and man-made chemicals have been shown to function as “endocrine disrupters” in experimental systems, and some adverse reproductive effects in wildlife have been linked to the presence of these chemicals in the environment (129–133). Although similar adverse effects, including teratogenesis, have been suggested in humans, a measurable impact at the levels of exposure usually encountered seems unlikely (134).

There has been considerable concern about maternal exposures to other environmental contaminants, but there is no compelling evidence of teratogenic effects of such exposures in humans. Adequate studies are often difficult to perform because of uncertainty about the magnitude of individual exposures and the causal heterogeneity of birth defects. Avoiding toxic exposures during pregnancy as much as possible is certainly a prudent precaution.

**36.3.3.2 Recreational Drugs.** Among the host of drugs that individuals in our society habitually use and abuse, alcohol and tobacco clearly stand out as the most important public health problems for both adults and the developing embryo or fetus. Adverse effects on the offspring have also been associated with maternal abuse of cocaine and some other “recreational” drugs during pregnancy.

**36.3.3.2.1 Ethyl Alcohol.** Ethanol leads the list of abused drugs in the United States and many other parts of the world. Thus, it is perhaps surprising that recognition

of the adverse effects of this agent on fetal growth and development did not occur sooner. Historical reviews suggest that such a possibility was indeed recognized by at least some individuals for hundreds if not thousands of years (135,136). However, the studies of Smith and Jones (40,137) and others (138–140) during the 1970s led to general acceptance of the teratogenic potential of maternal alcohol abuse during pregnancy. Pathogenesis, treatment, and prevention of alcohol-related birth defects are now subjects of intensive investigation, and recognition of the fetal alcohol syndrome has resulted in important changes in public policy and social norms regarding drinking by pregnant women (136,141,142).

Prenatal exposure to ethanol can result in a wide spectrum of effects on the embryo and fetus. The frequency and severity of these anomalies appear to be dose related. They range from apparently unaffected children to severely affected individuals with the fetal alcohol syndrome. Severe fetal alcohol syndrome occurs among infants born to chronically alcoholic women, but there is considerable disagreement about the amount of ethanol necessary to cause milder degrees of fetal damage (143–147). Some evidence suggests that consumption of as little as two drinks per day or periodic binge drinking (e.g. five or more drinks on a single occasion) in early pregnancy may be associated with recognizable (though milder) abnormalities in a significant percentage of exposed newborns. Full clinically recognizable fetal alcohol syndrome occurs in about 6% of children of women who drink heavily during pregnancy, although the risk is much higher for alcoholic women who have already had an affected child. Less-severe alcohol-related birth defects and neurocognitive deficits occur in a much larger proportion of these children, but the estimated frequency varies widely in different studies. The effects are less severe among the children of alcoholic women who stop drinking early in pregnancy.

The fetal alcohol syndrome is characterized by a distinctive facial appearance, prenatal-onset growth deficiency, developmental delay and intellectual disability, and an increased frequency of major congenital anomalies (147–150). Children with this syndrome display a flat midface with narrow palpebral fissures, a low nasal bridge, short upturned nose, and long smooth philtrum with a narrow vermilion border of the upper lip. Presenting as small-for-gestational-age babies in the neonatal period, they continue to grow poorly and often are admitted to the hospital for evaluation of “failure to thrive.” They may be described as jittery or tremulous babies, a feature that often results in confusion with drug-withdrawal symptoms. However, these neurologic abnormalities persist, and, in addition to having developmental delay and intellectual disability, such children are often poorly coordinated, tremulous, and sometimes hyperactive in later life. A wide variety of congenital anomalies has been associated with this syndrome, including cleft palate, cardiac malformations (especially

atrial and ventricular septal defects), microphthalmia, joint anomalies, and a variety of dermal and skeletal abnormalities. Cranial MRI often shows abnormalities of neuronal migration, occasionally associated with microcephaly, hydrocephalus, absence of the corpus callosum, other midline anomalies, or cerebellar abnormalities (151,152). Maternal alcohol use during pregnancy has been associated with an increased risk of stillbirth in some studies (153,154).

Other studies have reported associations between acute myeloid leukemia and other malignant neoplasms in the offspring and maternal drinking during pregnancy, although these associations have not always been found (155,156). If an association between maternal drinking and development of malignancy in the children does exist, the risk is probably substantially less than 1%.

Epidemiologic studies suggest that prenatal damage from maternal alcohol abuse may be one of the most frequent recognizable causes of intellectual disability in the United States (157). Disabilities due to prenatal alcohol abuse are an important public health problem (157)—an observation that is particularly distressing because virtually all such exposures are avoidable. Pregnant women, or women who might become pregnant, should avoid drinking alcohol as much as possible—the safest amount being none at all.

**36.3.3.2 Tobacco Smoking.** Maternal smoking during pregnancy interferes with fetal growth (158,159). Birth weight, length, and head circumference tend to be decreased in exposed babies. This growth deficiency is dose related and reversible in early childhood, although obesity appears to be more frequent than expected among the offspring of women who smoked during pregnancy (160). Women who smoke heavily during pregnancy also have higher-than-expected rates of spontaneous abortion, late fetal death, neonatal death, and prematurity (161).

Slightly lower measured intelligence levels and increased frequencies of hyperactivity have been reported in these children (162,163). Maternal smoking during pregnancy has also been associated with a small increase in some birth defects, especially cleft lip and palate and cleft palate alone (164). The risk appears to be greater among a subset of infants who have genetic variants that predispose to orofacial clefting (165,166).

The common association between smoking and concomitant alcohol and other drug abuse raises concern about potential interactive effects between tobacco and other potentially teratogenic exposures. Pregnant women should be advised to avoid smoking. Smokers who are unable to stop should be advised to reduce their smoking as much as possible, as this appears to improve fetal outcome.

**36.3.3.2.3 Cocaine.** The extensive medical literature on the effects of maternal cocaine use in pregnancy is difficult to interpret (167,168). Most studies are bedeviled by confounding factors, deficiencies in design, and poor documentation of the frequency, timing, and

dosage of the mothers' use of cocaine, other illicit drugs, and alcohol. Moreover, there appears to be a systematic publication bias in favor of studies that show an association and against those that do not find an association between maternal cocaine use and untoward pregnancy outcomes (46,169).

Vascular disruptions occur with increased frequency in infants whose mothers abused cocaine during pregnancy, especially in the second or third trimester. Involvement of the central nervous system has been reported most often (170). Other congenital anomalies thought to result from vascular disruption—segmental intestinal atresia, gastroschisis, sirenomelia, limb-body wall complex, and limb reduction defects—have also been associated with maternal abuse of cocaine during pregnancy in some studies (170). Associations with other kinds of congenital anomalies have been reported as well, but the findings are inconsistent. Cocaine's vasoconstrictive and hypertensive actions probably account for the increased frequency of placental abruption observed among pregnant women who abuse this drug (171).

Prenatal growth retardation has consistently been noted among infants whose mothers abused cocaine during pregnancy, but the effect appears to be due at least in part to concomitant exposure to alcohol or cigarette smoking (144). By school age, the growth of these children is indistinguishable from controls in most studies (172).

Many studies have demonstrated a subtle pattern of neonatal behavioral abnormalities among infants born to women who abused cocaine during pregnancy (170). This pattern has been characterized as affecting “the four A's of infancy”: attention, arousal, affect, and action. Studies in older children have been inconsistent, and interpretation is confounded by other differences that distinguish mothers who abuse cocaine during pregnancy from other women (170,172,173).

**36.3.3.2.4 Toluene Abuse.** Maternal abuse of toluene by inhalation during pregnancy can produce a characteristic toluene embryopathy in the offspring (174–176). Affected children exhibit central nervous system dysfunction, developmental delay, attention deficit disorder, microcephaly, growth deficiency, short palpebral fissures, deep-set eyes, micrognathia, abnormal auricles, and small fingernails. The features resemble fetal alcohol syndrome. Toluene embryopathy is associated with maternal inhalation of toluene in acute doses that may be 10–100 times greater than the occupational limit, which is averaged over a workday. Adverse fetal effects are unlikely with maternal exposure to less than the occupational limit of toluene during pregnancy, but it is prudent to avoid such exposure if possible.

**36.3.3.2.5 Other Drugs of Abuse.** Although many conflicting claims have been made regarding the “recreational” use of drugs such as amphetamines, LSD, and other hallucinogens, there is little objective evidence that implicates maternal abuse of such drugs as a cause of

birth defects (177,178). Maternal drug abuse during pregnancy is associated with fetal growth retardation, increased perinatal mortality, and neonatal behavioral abnormalities, including drug withdrawal (177–179). Children of women who abuse drugs during pregnancy are clearly at increased risk for adverse outcomes, but it is difficult to determine whether these are effects of the drugs themselves or of social problems, infectious diseases, poor nutrition, or abuse of alcohol or cocaine, all of which often accompany other drug abuse. For many reasons, including potential hazards to the fetus associated with all these factors, pregnant women should not abuse drugs.

**36.3.3.2.6 Caffeine.** While caffeine is teratogenic in high doses in some species, no convincing evidence linking this substance to human congenital anomalies has emerged (180,181). Associations between maternal coffee drinking during pregnancy and miscarriage or poor fetal growth have been repeatedly observed in epidemiological studies, but these studies are often confounded by cigarette smoking and other factors (181,182). It is unlikely that moderate coffee drinking by pregnant women adversely influences fetal growth or the rate of miscarriage, but it is sensible for pregnant women to avoid excessive caffeine intake.

**36.3.3.3 Nonprescription Drugs.** Many over-the-counter preparations are widely used for the treatment of viral illnesses, allergies, headache, aches and pains, sleep disturbances, anxiety, and gastrointestinal discomfort. Little formal evaluation has been conducted of the potential reproductive toxicity of most over-the-counter drugs. In the absence of specific information, it seems prudent to avoid these medications whenever possible, particularly in the earliest part of pregnancy.

**36.3.3.3.1 Salicylates and Other Anti-inflammatories.** Although aspirin and other salicylate compounds are believed to be among the safest and most effective drugs in the marketplace, excessive use during pregnancy may be associated with an increased risk of fetal hemorrhages, and limited evidence suggests that chronic aspirin consumption may interfere with fetal growth (183,184). Malformations, in general, do not appear to be associated with the prenatal use of salicylates (184,185), but there is evidence that gastroschisis may be about three times more common among the infants of mothers who take aspirin early in pregnancy (184). No consistent evidence of an effect on intelligence has been identified (186,187).

Epidemiological studies of children whose mothers took acetaminophen during the first trimester of pregnancy have found no consistent association with birth defects (188,189).

The available data regarding maternal use of ibuprofen during pregnancy are more limited, but treatment during the first trimester seems unlikely to pose a major teratogenic risk (190). A small increase in certain kinds of cardiac malformations has been found in some studies

but not others. However, neonatal renal failure, oligohydramnios, and in utero closure of the ductus arteriosus have been associated with maternal ibuprofen treatment to arrest premature labor later in pregnancy (191).

**36.3.3.4 Prescription Drugs.** Half of all pregnant women take at least one prescription medication during the first trimester (192,193). Treatment with some prescription medications is potentially teratogenic when used at conventional therapeutic doses. Other drugs can be used safely during pregnancy, and in some instances, such treatment is highly beneficial to both the mother and the fetus. Unfortunately, however, available data are insufficient to determine whether maternal treatment with most prescription drugs during pregnancy poses a substantial teratogenic risk. Postmarketing studies of prescription drugs for potential teratogenicity need to be greatly expanded to permit more adequate counseling of pregnant women. In the absence of specific information strongly supporting the safety of treatment with a particular agent during pregnancy, prudence dictates that such treatment be avoided whenever possible. All women of reproductive age who are given prescription drugs should be counseled regarding the potential teratogenic effects, because many exposures occur when women become pregnant unintentionally or before they recognize that they are pregnant.

**36.3.3.4.1 Thalidomide.** The most dramatic epidemic of drug-induced birth defects ever recognized occurred in the early 1960s when thalidomide was sold in several countries, but not the United States, as an over-the-counter sedative. The dramatic events that followed are now a matter of historical record: over 10,000 babies were damaged by this drug between 1958 and 1963. The association between maternal thalidomide treatment and birth defects was independently noted by Widukind Lenz (1962) and William McBride (1961). Subsequent studies indicated that the susceptible period for the embryo was between 20 and 35 days after conception (17).

The thalidomide embryopathy includes a very unusual and characteristic pattern of congenital anomalies (42). The manifestations depend primarily on the stage of embryonic development at which the exposure occurred. Typical anomalies are phocomelia and other limb reduction malformations, anomalies of the external ear, ocular anomalies, and cardiovascular malformations ranging from septal defects to complex conotruncal defects. Involvement of the central nervous system and other organ systems may occur but is less common.

For many years after the recognition of thalidomide embryopathy, the drug was not marketed in most countries. However, the discovery of thalidomide's immunomodulatory action has led to its use in a variety of neoplasms and immunopathic disorders, including AIDS. Currently, it is being prescribed in the United States and other countries under strict controls designed to avoid use by pregnant women.

#### **36.3.3.4.2 Folic Acid Antagonists.**

**36.3.3.4.2.1 Trimethoprim and Other Weak Folic Acid Antagonists.** A 60–80% increase in the frequency of birth defects has been observed among the infants of women who were treated with trimethoprim, an antibiotic that acts as a weak dihydrofolate reductase inhibitor, during the first trimester of pregnancy (194). The risk among these infants appears to be greatest for neural tube defects, cardiovascular malformations, oral clefts, and urinary tract defects, which occur two to five times more often than expected (194–196). Similar associations have been found among infants whose mothers were treated early in pregnancy with other weak folic acid antagonists such as triamterene, sulfasalazine, and anticonvulsant agents (195,197). These risks are reduced if the mother also takes a folic acid supplement early in pregnancy (194,195,197).

**36.3.3.4.2.2 Aminopterin and Methotrexate.** An unusual and characteristic pattern of congenital anomalies has been reported in more than two dozen children whose mothers took aminopterin or methotrexate during pregnancy. In addition to its use as an antineoplastic agent, methotrexate is employed in the therapy of rheumatoid arthritis and other immunopathic diseases and as part of a medical regimen to induce abortion.

Children with aminopterin or methotrexate embryopathy have distinctive craniofacial anomalies with abnormal head shape and ocular hypertelorism, shallow orbits, mild midfacial hypoplasia, micrognathia, cleft palate, and facial asymmetry (198–200). Malformations of the auricles, skin tags, and numerous skeletal anomalies, especially vertebral segmentation abnormalities with anomalous ribs, abnormalities of ossification of sacral structures, ectrodactyly, syndactyly, longitudinal limb reduction malformations, and positional limb deformities are common. Central nervous system abnormalities, may occur, and developmental delay is the rule in childhood. However, affected adults may have normal or only mildly reduced intelligence. Women who are treated with methotrexate or aminopterin in pregnancy have increased rates of miscarriage, early fetal growth retardation, stillbirth, and neonatal death.

The risk of a teratogenic effect after first-trimester maternal treatment with methotrexate is probably dose related, and much lower doses of the drug are used to treat immunopathic diseases than neoplasia. Most babies born to women treated with low-dose methotrexate during pregnancy appear normal at birth (201), but typical folic acid embryopathy has been reported even with low-dose treatment (202,203). This may reflect a particular genetic susceptibility.

**36.3.3.4.3 Anticancer Agents.** As the therapeutic efficacy of antineoplastic agents is dependent on their ability to kill cells, particularly undifferentiated cells, treatment with any of these agents should be regarded as potentially teratogenic. The strong folic acid antagonists and several of the alkylating agents, in particular, have

caused concern (199,204). Maternal treatment early in pregnancy with various cancer chemotherapeutic agents has been anecdotally associated with a variety of fetal anomalies, including severe intrauterine growth retardation, microphthalmia, cleft palate, genitourinary anomalies, and limb reduction defects (199,204). The risk for such exposure to produce malformations has not been clearly defined, but the early stage of pregnancy appears to be a particularly hazardous time.

Treatment with high doses of most anticancer agents is teratogenic in laboratory animals (199). Unlike most kinds of drug therapy, cancer chemotherapy is often given at the maximum dose tolerated by the mother, i.e. the doses are near or within the range of maternal toxicity. Under such conditions, treatment may carry a substantial risk of teratogenic effects, especially when it occurs during the first trimester and with several drugs at once. However, apparently normal children have been born to women who underwent cancer chemotherapy during the first trimester or later in pregnancy (204–206), and the risk of teratogenic effects in a particular case depends on the agent or combination of agents, dose, route, and gestational timing in a complex way that is unique for almost every woman.

In general, the risk of miscarriage appears to be increased with many kinds of cancer chemotherapy during the first trimester of pregnancy, and the risks of premature delivery and fetal death, growth retardation, and myelosuppression may be increased with treatment later in pregnancy (205,206). Women who are undergoing cancer chemotherapy should be advised to avoid pregnancy during the period of treatment. Patients who require such treatment during pregnancy should receive appropriate counseling regarding the risk of congenital anomalies and other adverse effects in exposed offspring.

**36.3.3.4.3.1 Trastuzumab (Herceptin®).** Anhydramnios and oligohydramnios are frequent in pregnancies in which the mother was treated with trastuzumab during the second trimester (207,208). Oligohydramnios may resolve if the trastuzumab treatment is discontinued, but in some instances, renal failure may occur in the newborn. Little information is available on the effect of first-trimester maternal trastuzumab treatment on embryonic development.

**36.3.3.4.4 Warfarin Anticoagulants (Coumadin®).** A striking pattern of congenital anomalies, which is otherwise quite rare, has been reported repeatedly among children whose mothers were treated with coumarin derivatives during pregnancy (Figure 36-2) (209,210). Affected children typically have abnormal facial features with severe nasal hypoplasia, which may also affect the ethmoid complex and result in choanal atresia. Microcephaly is common, and optic atrophy has been repeatedly observed. Radiographic studies often reveal a lag in skeletal maturation with stippling of epiphyseal growth centers. Prenatal-onset growth deficiency with subsequent failure to thrive, developmental delay, intellectual

**FIGURE 36-2** Fetal warfarin syndrome, note severe nasal hypoplasia. (From Pauli et al. (360), with permission.)

disability, and other neurologic abnormalities are frequent features. Other serious congenital anomalies are less frequent.

The period of greatest concern for the production of fetal facial and skeletal anomalies is from 6 to 9 weeks after conception. Beyond 9 weeks of age, ocular defects and central nervous system malformations may be produced. Children with these abnormalities often have a poor outcome, although survivors who do not have intellectual disability usually do relatively well except for their craniofacial abnormalities. Children with similar defects whose mothers did not take coumarin derivatives during pregnancy have been described who have a genetic disorder of vitamin-K-dependent coagulation factors (211,212), suggesting that bleeding into developing tissues may be pathogenic in coumarin embryopathy.

The frequency of coumarin embryopathy among infants of women who are treated with warfarin throughout pregnancy has been estimated to be 3–6% (213,214). Miscarriage appears to occur more often than expected when the mother is treated with coumarin derivatives early in pregnancy. Stillbirth and fetal, placental, and neonatal hemorrhage are substantially more frequent when the mother is treated with coumarin anticoagulants late in pregnancy (213).

**36.3.3.4.5 Antibiotics and Other Anti-infective Agents.** Available studies have not revealed an increased risk to the fetus associated with prenatal treatment with most anti-infective agents, including

penicillins, sulfonamides, cephalosporins, or related agents (215,216). Exceptions to this generalization are treatment with trimethoprim, a folic acid antagonist discussed above, or with tetracyclines, aminoglycosides, high-dose quinine, or high-dose fluconazole. Most newer antibacterial and antiviral agents have not been adequately studied with regard to their teratogenic potential in human pregnancy.

**36.3.3.4.5.1 Tetracyclines.** Maternal treatment with tetracyclines during the second and third trimesters of pregnancy produces staining of the infant's primary teeth (217). The risk for malformations does not appear to be increased among the children of women who were treated with tetracyclines during pregnancy.

**36.3.3.4.5.2 Aminoglycosides.** Several cases of sensorineural deafness, sometimes with accompanying vestibular dysfunction, have been reported in children whose mothers were treated during pregnancy with streptomycin (218). Asymptomatic abnormalities of auditory or vestibular function have been observed in up to 10% of such children, but symptomatic disturbances of eighth cranial nerve function are much less common (219).

**36.3.3.4.5.3 Quinine and Related Antimalarials.** Maternal use of very high doses of quinine in an attempt to induce abortion have been associated with deafness and optic nerve abnormalities in the offspring in case reports and clinical series (220). A causal association seems possible because quinine treatment, especially in large doses, may cause auditory and visual damage in adults. Such abnormalities do not appear to be unusually common among the children of pregnant women who are given much lower doses of quinine to treat malaria or who take the usual prophylactic or therapeutic doses of chloroquine (221).

**36.3.3.4.5.4 Fluconazole.** A few children have been described with a very unusual pattern of congenital anomalies whose mothers were treated for coccidioidomycosis meningitis during the first trimester of pregnancy with daily high-dose fluconazole (222). The features in these infants include brachycephaly, abnormal calvarial development, cleft palate, arthrogryposis, and congenital heart disease. The pattern of anomalies resembles the Antley-Bixler syndrome, an autosomal recessive condition, but the occurrence of a similar rare pattern of congenital anomalies in children whose mothers received the same, very unusual, treatment during pregnancy suggests a causal relationship. A teratogenic effect is unlikely with the much lower doses of fluconazole used to treat vaginal candidiasis (223).

**36.3.3.4.6 Anticonvulsants.** Because seizures affect 0.5–1.0% of pregnant women, the potential teratogenicity of anticonvulsants has been a source of substantial concern for several decades. Although there was confusion in the past about the relative contribution of the underlying convulsive disorder and that of the medications used to treat it, a consensus has now emerged that treatment of pregnant women with a number of different

anticonvulsant medications increases the risk for fetal abnormalities two to three times that of the normal population. The risk is higher in women who require treatment with multiple anticonvulsants, especially combinations that include valproic acid, than in those who are adequately treated with a single medicine (224–226).

Various anticonvulsant agents are now being used for the treatment of bipolar disorder, neurogenic pain, and other conditions, but it is not known if the teratogenic potential of these drugs is different when they are used during pregnancy for indications other than control of seizures.

It seems prudent to suggest that all epileptic women be cautioned before beginning pregnancy about the potential adverse outcomes for their offspring. In some instances, a trial off drug therapy before conceiving may be warranted. In other cases, where it is deemed unsafe to take a woman off anticonvulsant therapy, she should be placed on the smallest number of agents and the lowest dosages compatible with adequate seizure control, and the potential hazards of anticonvulsant therapy to her offspring should be discussed in detail.

Maternal serum  $\alpha$ -fetoprotein measurement and detailed ultrasound examination are useful for prenatal diagnosis of fetal neural tube defects associated with maternal valproic acid or carbamazepine treatment during pregnancy (227). Some other serious malformations have also been diagnosed prenatally in fetuses of women treated with anticonvulsant medications during pregnancy, but the subtle dysmorphic syndromes and functional deficits that occur more frequently in these children cannot usually be identified before birth.

Many of the same major malformations and a similar pattern of minor anomalies, sometimes called the “fetal anticonvulsant syndrome,” have been reported among children of epileptic women treated with a variety of anticonvulsant medications (228). The discussion below emphasizes these similarities as well as some serious malformations that are only associated with maternal use of particular drugs during pregnancy.

**36.3.3.4.6.1 Trimethadione.** Trimethadione is the only oxazolidine anticonvulsant that is still used clinically. It is prescribed infrequently, usually for the treatment of petit mal epilepsy—an uncommon seizure disorder among women of reproductive age. There is little justification for use of this particularly toxic drug in pregnant women. Nevertheless, trimethadione is important because it was the first maternal anticonvulsant treatment found to produce a unique pattern of abnormalities of growth and development in infants exposed prenatally (229,230). Moreover, maternal trimethadione treatment during pregnancy, especially when used in combination with other drugs, appears to cause serious birth defects in an unusually large proportion of exposed pregnancies (231,232).

**36.3.3.4.6.2 Hydantoin Anticonvulsants.** The fetal hydantoin syndrome, a recurrent pattern of minor

anomalies that occurs in about 10% of infants born to epileptic women treated with phenytoin during pregnancy, has been recognized for more than 35 years (233). An additional 30% of children who are exposed during embryonic development show lesser degrees of alteration. The abnormalities found in children with fetal hydantoin syndrome include a characteristic facial appearance with midface hypoplasia, low nasal bridge, ocular hypertelorism, and an accentuated cupid's bow of the upper lip (Figure 36-3) (234,235). Prenatal-onset growth deficiency, including poor growth for weight, length, and head circumference, is occasionally seen. Increased frequencies of distal digital hypoplasia and of major malformations, particularly clefts of the lip and palate and cardiovascular anomalies, have been noted (235,236). In addition, small but significant reductions in cognitive function have been observed among the children of epileptic women treated with phenytoin during pregnancy (237). Genetic differences in maternal or fetal metabolism appear to be important risk factors for congenital anomalies among the children of epileptic women treated with phenytoin during pregnancy (11,238).

Children whose mothers were treated with phenytoin during pregnancy also have a higher-than-expected risk of developing neuroblastoma (239). Fortunately, neoplasia is rare in childhood, and such tumors are uncommon even in children whose mothers took phenytoin during pregnancy.

**36.3.3.4.6.3 Valproic Acid.** A characteristic pattern of craniofacial and other anomalies has been observed in up to half of children born to epileptic women treated with valproic acid during pregnancy (228,240,241). Features of this "fetal valproate syndrome" include

abnormalities of the calvaria with metopic ridging, trigonocephaly, narrow bifrontal diameter, relative deficiency of the outer orbital region, midfacial hypoplasia, short upturned nose with a broad flat bridge, and long flat philtrum with a thin vermilion border of the upper lip.

Major malformations occur in about 10% of infants whose mothers are treated with valproic acid for epilepsy during the first trimester of pregnancy; the rate is higher than that associated with most other anticonvulsants (225,240,242,243). The risk of spina bifida is about 2% among these children. The risk for anencephaly does not appear to be increased, suggesting that the pathogenetic mechanism may not be related to neural tube closure but rather to factors that affect canalization caudal to the posterior neuropore. Inherited variations in maternal drug metabolism may increase the susceptibility of certain pregnancies to these adverse effects (240,244).

**36.3.3.4.6.4 Carbamazepine.** A fetal anticonvulsant syndrome has also been observed among the children of epileptic women who were treated with carbamazepine during pregnancy (228). The features include minor craniofacial anomalies, fingernail hypoplasia, and delayed growth and development. The frequency of major malformations among the children of epileptic women treated with carbamazepine during pregnancy appears to be similar to that observed in children of women treated with other anticonvulsants (225,242,243). Spina bifida occurs in about 1% of children whose mothers took carbamazepine while they were pregnant.

**36.3.3.4.6.5 Other Anticonvulsant Agents.** Phenobarbital is not often used as an anticonvulsant in adults, but primidone, which is partially metabolized to phenobarbital, is sometimes used. In most studies, the frequency of congenital anomalies among children of

**FIGURE 36-3** Features of the fetal hydantoin syndrome. (A) Facial and (B) digital. Note the ocular hypertelorism, ptosis and strabismus, short nose with low bridge, and accentuated "cupid's bow" of lip. Distal phalangeal and nail hypoplasia are common digital anomalies. (From Hanson (234), with permission.)

epileptic women treated with these drugs during pregnancy is similar to that observed with other anticonvulsants and greater than that expected without such treatment (225,242,243,245). A distinctive pattern of minor dysmorphic features and poor growth, i.e. a “fetal anticonvulsant syndrome” occurs in some children whose mothers were treated for epilepsy with either phenobarbital or primidone during pregnancy (228,235).

Insufficient data are available to determine the risk of congenital anomalies in the children of pregnant women treated with the succinimide anticonvulsants, ethosuximide or methsuximide. Treatment of maternal epilepsy with lamotrigine during pregnancy appears to be associated with similar rates of congenital anomalies among the infants as treatment with older anticonvulsants (225,242,243). Information available on the teratogenic potential of other more recently developed anticonvulsants, including vigabatrin, topiramate, felbamate, gabapentin, clobazam, and clonazepam, is limited. It is not yet known if the risk of birth defects among the children of women who are treated with these newer drugs during pregnancy is higher, lower, or similar to that of children whose mothers took conventional anticonvulsants. Registries have been established in the United States (<http://www.mgh.harvard.edu/aed/>) and other countries to collect and disseminate information on the teratogenic potential of maternal treatment with anticonvulsant agents during pregnancy.

**36.3.3.4.7 Endocrine Agents.** A number of reports have suggested possible teratogenic effects of agents used for treatment of endocrine disorders. These drugs are often taken by women of reproductive age.

**36.3.3.4.7.1 Female Sex Hormones.** Agents with female sex-hormone-like activity, especially various synthetic progestins and estrogens, have received considerable attention because of their widespread use as contraceptive agents and for other medical purposes that could result in fetal exposures.

**36.3.3.4.7.1.1 Diethylstilbestrol.** Diethylstilbestrol (DES) was widely used in the 1950s as a treatment for threatened abortion and for estrogen replacement during pregnancy. The daughters of women who received such treatment during pregnancy have a greatly increased risk of gross structural anomalies of the uterus and vagina and of developing vaginal adenosis and clear cell adenocarcinoma of the vagina or cervix (246,247). At least one-third to one-half of women who were exposed in utero to diethylstilbestrol have gross or histological abnormalities of the genital tract, but the absolute risk of developing vaginal malignancy is fortunately quite small. Ectopic pregnancy, miscarriage, and premature delivery also occur with increased frequency among “DES daughters.” The sons of women who were treated with DES during pregnancy have higher-than-expected frequencies of epididymal cysts, hypoplastic testes, and cryptorchidism, but fertility and sexual function are usually not impaired (246).

**36.3.3.4.7.1.2 Other Estrogens and Progestins.** Other estrogens have not been clearly associated with similar risks. Early reports of reduced masculinization of male fetuses after maternal treatment with other estrogens during pregnancy have not been substantiated.

Maternal treatment during pregnancy with high doses of androgenic progestins is associated with an increased risk of masculinization of the external genitalia in female fetuses. The degree of masculinization depends on the time of treatment and is unlikely to occur after the 12th week of gestation. The magnitude of this risk is no more than 1% with high doses and is less with lower doses. Maternal treatment with high doses of norethindrone is particularly likely to produce such abnormalities (248). Despite reports associating maternal progestin use during pregnancy with various other malformations in the offspring, no consistent pattern of abnormalities has emerged, and most epidemiologic studies have failed to confirm such associations.

Combinations of estrogens and lower-dose progestins in the form of contraceptive agents have also been alleged to produce fetal anomalies when taken after conception. Studies claiming a relationship between maternal use of these agents and various congenital anomalies have been reported, but the results have generally not been reproducible (248,249). A woman who has inadvertently become pregnant while taking an oral contraceptive can be reassured that her use of birth control pills is very unlikely to have harmed the fetus.

#### **36.3.3.4.7.2 Other Endocrine-Active Agents.**

**36.3.3.4.7.2.1 Clomiphene.** Induction of ovulation with clomiphene has been associated with an increased risk of neural tube defects in some studies, but most investigations do not show such an association (250,251). The effects of treatment with this agent are often confounded with the effects of underlying maternal disorders that led to the need for therapy.

About 5–10% of pregnancies that result from ovulation induced by clomiphene treatment are multifetal (252,253), and these twin, triplet, or higher multiple pregnancies are at increased risk for premature delivery and positional limb deformations.

**36.3.3.4.7.2.2 Male Sex Hormone Agents.** Maternal treatment with androgens during pregnancy can cause masculinization of the external genitalia of female fetuses (248). The effect appears to be dose related. Similar masculinization of female fetuses may occur after maternal treatment with large doses of anabolic steroids such as danazol, which have androgenic and antiestrogenic activity (254). No clear evidence of other teratogenic effects of androgens has been reported.

**36.3.3.4.7.2.3 Corticosteroids.** Some epidemiological studies have found an association of maternal treatment with systemic corticosteroids early in pregnancy with orofacial clefts in the offspring (255–257). Even if this association is real and causal, the absolute risk for orofacial clefts among children of women who are

treated with systemic corticosteroids during the first trimester would be less than 1% (258). The risk for malformations of other kinds does not appear to be substantially increased in these children (259).

**36.3.3.4.7.2.4 Antithyroid Agents.** Maternal treatment during pregnancy with antithyroid agents such as radioactive iodine ( $^{131}\text{I}$ ), propylthiouracil, or methimazole is associated with an increased risk of hypothyroidism and consequent intellectual disability in the offspring (260). In addition, it appears that maternal treatment with methimazole or the related thioamide, carbimazole, during pregnancy can occasionally cause cutis aplasia of the scalp or, rarely, a methimazole embryopathy in the fetus (261,262). The features of this unusual pattern of anomalies include developmental delay, choanal atresia, esophageal atresia, absent or hypoplastic nipples, and scalp defects. Congenital goiter, hypothyroidism, or both may also occur among the children of women treated with methimazole or carbimazole during pregnancy (263).

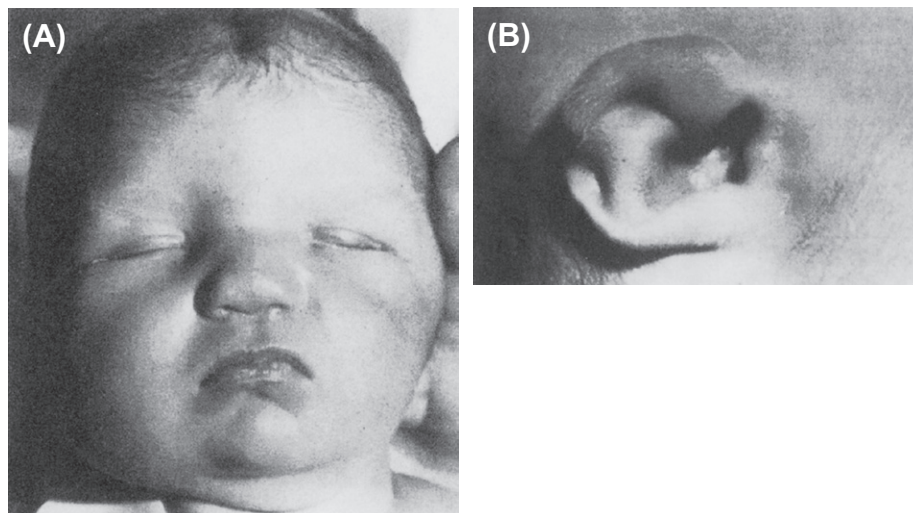

Iodides have the potential of producing neonatal goiter and hypothyroidism, particularly when taken by a pregnant woman after the first trimester (260). Fetal goiter can also be produced by maternal treatment with other medications, such as amiodarone, that contain large amounts of iodine (264).

**36.3.3.4.8 Retinoids and Vitamin A.** Preformed retinoids, including retinol, retinaldehyde, and retinoic acid, possess vitamin A activity directly. They are contained in substantial amounts in some foods, especially liver. Isotretinoin, etretinate, and acitretin are synthetic retinoid congeners that are used orally and topically to treat a variety of skin disorders. Absorption of the topical forms is usually quite limited.  $\beta$ -Carotene and related carotenoids, which are contained in many orange or dark green leafy vegetables, can be metabolized by the body to vitamin A.

Although information linking the ingestion of large amounts of vitamin A to birth defects has been available in laboratory animals since the 1950s, the relevance of these observations to human beings remained uncertain until a characteristic pattern of birth defects was recognized in children whose mothers had been treated with isotretinoin during pregnancy (43). A large body of studies subsequently demonstrated the teratogenic potential of oral therapy with isotretinoin or etretinate, and anecdotal evidence suggests that acitretin and preformed vitamin A itself in very high doses may have similar potential (265–267).

The characteristic retinoid embryopathy has been most clearly delineated in children of women who were treated with isotretinoin during the first trimester of pregnancy (43,267). Typical craniofacial anomalies include microcephaly, facial asymmetry with midfacial hypoplasia and facial nerve palsy (Figure 36-4a), microphthalmia, cleft palate, micrognathia, and microtia (Figure 36-4b) or anotia. Central nervous system abnormalities, such as hydrocephalus or posterior fossa cysts, and cardiovascular malformations, especially conotruncal defects, are common. Thymic hypoplasia and genitourinary anomalies, including hypoplastic kidneys and hydroureter, are also frequent. Children with isotretinoin embryopathy who survive often have intellectual deficiency (268).

Dosage and timing are major factors, the highest risk being with maternal treatment between 2 and 5 weeks after conception. However, it should be noted that both etretinate and retinol have half-lives of weeks to months, leading both to longer risk periods after discontinuation of use and the possibility of substantial bioaccumulation (269). The half-life of isotretinoin is much shorter—less than 1 day. Despite a program designed by the manufacturer to prevent use of isotretinoin in pregnancy, substantial numbers of fetal exposures continue to occur (270–272). Women who are pregnant or may become

**FIGURE 36-4** Fetal retinoid syndrome. (A) Dysmorphic facial features and (B) Microtia. ((A) From Lammer (361), with permission; (B) From Fernhoff and Lammer (362), with permission.)

pregnant should not be treated systemically with isotretinoin or related drugs.

Concern about the teratogenic potential of preformed vitamin A in doses as low as 10,000 IU/day has been raised (273) but appears to be unfounded (266,274,275). An exact threshold dose for the teratogenic risk associated with use of preformed vitamin A in pregnancy has not been determined but is likely to be greater than 30,000 IU/day. Nevertheless, pregnant women should not take more than the recommended dietary allowance of preformed vitamin A (266,276). Liver contains large amounts of retinol, and it has been recommended that pregnant women avoid eating excessive amounts of liver during pregnancy (277).

Ingestion of  $\beta$ -carotene, even in high doses, has not been associated with a teratogenic risk (266,278). Vitamin supplements containing  $\beta$ -carotene are, therefore, preferable to those containing preformed vitamin A for women of reproductive age.

**36.3.3.4.9 Lithium.** Children of women who are treated with lithium during pregnancy appear to have an increased risk of Ebstein's anomaly of the heart, although epidemiological studies indicate that this risk is likely to be small (27–29). Fetal echocardiography should be offered to women who are treated with lithium during the first trimester of pregnancy for prenatal diagnosis of fetal cardiac disease.

Treatment of severe depression in pregnant women and those of reproductive age presents a clinical dilemma. The small but serious teratogenic risk associated with lithium use may need to be balanced against a substantial risk to the mother's health if treatment is stopped and against possible maternal or fetal risks associated with alternative treatments (279,280).

**36.3.3.4.10 Selective Serotonin Reuptake Inhibitors.** Selective serotonin reuptake inhibitors (SSRIs) are very widely used as antidepressants. These drugs are also given to treat obsessive compulsive disorder, panic disorders, and other psychiatric illnesses. Several large epidemiological studies have found associations between maternal treatment with SSRIs, especially paroxetine, during early pregnancy and cardiac malformations or other birth defects in the infant, but other studies have not shown such associations (281–286). Although interpretation of these data remains controversial, it seems likely that the frequency of congenital anomalies among children of women who take an SSRI during the first trimester of pregnancy is increased by only a small amount overall. Transient behavioral alterations and other abnormalities of neonatal adaptation may occur in infants whose mothers were treated with an SSRI close to the time of delivery.

**36.3.3.4.11 Codeine and Other Opioid Analgesics.** A small increase in the frequency of congenital heart defects has been observed repeatedly in case-control studies of children whose mothers had been treated with codeine or another opioid analgesic early in pregnancy

(287–290). An increased frequency of spina bifida or cleft lip and palate has also been observed in some studies but not others (290–293). Even if all observed associations are causal, the overall increase in the risk of congenital anomalies among infants of women who took opioid analgesics early in pregnancy is probably less than 1%.

Narcotic withdrawal symptoms may occur in newborn infants whose mothers were treated chronically with opioid analgesics late in pregnancy (294).

**36.3.3.4.12 Misoprostol.** Misoprostol is a prostaglandin analog that is used in the prevention and treatment of peptic ulcer disease. The drug is also used in combination with mifepristone (RU-486), a progesterone blocker, to induce abortion. Associations have been observed between unsuccessful maternal use of misoprostol to induce abortion in the first trimester of pregnancy and the occurrence of Moebius syndrome, terminal transverse limb reduction defects, arthrogryposis, and brain defects such as holoprosencephaly and hydrocephalus in the offspring (295–297). Vascular disruption is a biologically plausible explanation for these associations (298). The risks of severe anomalies among fetuses surviving attempted induced abortion with mifepristone and misoprostol should be explained to women contemplating such treatment. These risks contribute to the recommendation that pregnancies that continue in spite of attempted medical abortion be surgically terminated.

Oral doses of misoprostol similar to those used for pregnancy termination are taken chronically for prophylaxis or treatment of peptic ulcer disease. Pharmacological induction of abortion and the teratogenic risks would be expected to be at least as great when the drug is taken early in pregnancy for peptic ulcer disease as when it is taken to induce abortion, but little information is available on the outcome of such pregnancies.

**36.3.3.4.13 Mycophenolate Mofetil.** An unusual pattern of malformations has been repeatedly observed among children whose mothers were treated with mycophenolate mofetil early in pregnancy (38,299–301). Frequent features include microtia or anotia, auditory canal atresia, conductive deafness, cleft lip, cleft palate, dysmorphic facial features of the face, congenital heart defects, and short fifth finger. The natural history of this embryopathy has not yet been delineated.

**36.3.3.4.14 Penicillamine.** Several infants whose mothers were treated with penicillamine during pregnancy have been reported to have an unusual syndrome resembling cutis laxa (see Chapter 155) (302,303). Although such connective tissue abnormalities are uncommon among the children of women who take penicillamine during pregnancy, a causal relationship seems likely. Similar skin abnormalities occur as a rare complication of chronic penicillamine therapy in adults, and such treatment is known to affect cross-linking of elastin and collagen.

### 36.3.3.4.15 *Inhibitors of the Renin-Angiotensin System.*

**36.3.3.4.15.1 Angiotensin-Converting Enzyme (ACE) Inhibitors.** Neonatal renal failure and hypotension as well as fetal anuria resulting in oligohydramnios, joint contractures, pulmonary hypoplasia, and death have been observed repeatedly after maternal treatment with captopril, enalapril, or lisinopril during pregnancy (304). Several cases of neonatal hypocalvaria and other skeletal anomalies have also been noted after maternal treatment during pregnancy with one of these ACE inhibitors. Accurate risk estimates are not available, but the effects appear to result from hypersensitivity of the fetus to the pharmacologic action of ACE inhibitors during the second half of pregnancy (304). There is some evidence suggesting that maternal ACE inhibitor therapy early in pregnancy increases the risk of cardiovascular and central nervous system malformations among infants (305), but further study is necessary to determine whether the observed associations are causal. Women who conceive while taking an ACE inhibitor should be switched during the first trimester to an antihypertensive agent of a different class if treatment continues to be necessary.

**36.3.3.4.15.2 Angiotensin II Receptor Inhibitors.** Losartan, candesartan, valsartan, and other antihypertensive drugs of the “sartan” class block the activity of the renin-angiotensin system by a mechanism different from ACE inhibitors. Several case reports describe oligohydramnios, fetal growth retardation, pulmonary hypoplasia, limb contractures, and calvarial hypoplasia in various combinations in association with maternal sartan treatment during the second or third trimester of pregnancy (304,306). Stillbirth or neonatal death is frequent in these reports, and surviving infants may exhibit renal damage. The fetal abnormalities, which are strikingly similar to those produced by maternal treatment with ACE inhibitors during pregnancy, are probably related to inhibition of the fetal renin-angiotensin system.

**36.3.3.4.16 Indomethacin and Other Prostaglandin Synthesis Inhibitors.** Maternal treatment with indomethacin late in pregnancy has been associated with decreased fetal urinary output and oligohydramnios, as well as with premature closure of the ductus arteriosus in the fetus and consequent persistent pulmonary hypertension in the infant (307). These effects appear to result from transplacental pharmacological activity of this prostaglandin synthesis inhibitor. Maternal treatment late in pregnancy with other inhibitors of prostaglandin synthesis, such as ibuprofen and ketoprofen, may have similar action on the fetal ductus arteriosus and kidneys (308). There is no indication that maternal treatment with these drugs early in pregnancy poses a substantial teratogenic risk.

**36.3.3.4.17 Methylene Blue.** Up to 20% of twins born after genetic amniocentesis in which methylene blue was used as a marker develop small bowel atresia (21). The affected twin was the one whose amniotic sac

was injected with the dye, and the risk appears to be greater with higher doses. The risk of fetal death was also increased after injection of methylene blue during genetic amniocentesis (309). It is important to note that these risks are only associated with intra-amniotic instillation of methylene blue, not with oral or topical use by the mother during pregnancy.

**36.3.3.4.18 Bendectin® (Diclectin®).** A fixed combination of pyridoxine (vitamin B<sub>6</sub>) and doxylamine (an antihistamine), marketed in the past as Bendectin® and more recently as Diclectin®, is used in the treatment of nausea and vomiting that are present during pregnancy. This medication was removed from the market by its manufacturer and has been unavailable for many years in the United States because of excessive litigation alleging that Bendectin® caused a variety of serious birth defects in children whose mothers took it early in pregnancy. However, extensive epidemiological studies provide no indication that maternal use of this medication during pregnancy increases the risk of congenital anomalies above the rate expected in the general population (310).

**36.3.3.5 Maternal Metabolic Factors.** Although not environmental in the strictest sense, factors that affect maternal metabolism may alter the intrauterine environment. Thus, an additional category of potential teratogenic effects is maternal metabolic factors. Of particular importance in this category is maternal diabetes mellitus, but maternal phenylketonuria (PKU) and inadequate folic acid intake are also of concern.

**36.3.3.5.1 Folic Acid Intake.** The recognition that the risk of many malformations, including neural tube defects, can be substantially reduced by maternal folic acid supplementation has provided an unparalleled opportunity for the prevention of birth defects. Dietary supplementation with folic acid before and after conception may reduce the overall risk of birth defects by 20% or more (311). Not all malformations are affected equally—neural tube defects may be reduced by as much as 85% (311–313), but the reductions in orofacial clefts, cardiac malformations, and renal anomalies are smaller (311,314). The mechanism of prevention is not understood (315,316), but certain genetic variants (e.g. in folate metabolism) may put some patients at greater risk than others for birth defects when folic acid supplementation is not provided (316,317).

All women of childbearing age should take 0.4 mg of supplemental folic acid daily (318). Larger doses of folic acid are sometimes recommended for women who are at increased risk of having a child with a neural tube defect. As compliance with regimens requiring daily vitamin supplements is problematical, grain products are fortified with folic acid in some countries (319).

**36.3.3.5.2 Diabetes Mellitus.** The principal maternal metabolic disorder that raises concern for the developing fetus is type 1 diabetes mellitus. The risk of congenital anomalies in infants of women who have insulin-dependent diabetes is two to three times greater

than that in the general population (320,321). A variety of congenital anomalies is associated with maternal diabetes, but congenital heart defects and neural tube defects are most common. Preconceptional and early postconceptional folic acid supplementation is, therefore, especially important for women with type 1 diabetes, and pregnant diabetic women should be offered prenatal diagnosis by detailed ultrasound examination, fetal echocardiography, and serum  $\alpha$ -fetoprotein measurement.

Caudal regression, focal femoral hypoplasia, and holoprosencephaly are also more frequent than expected among children of women with type 1 diabetes mellitus, but these malformations are, fortunately, uncommon. Diabetic pregnancies are at increased risk for spontaneous abortion, abnormal fetal growth, neonatal hypoglycemia, and various obstetrical complications (322,323). Risks for congenital anomalies and adverse neonatal outcomes can be minimized by very good control of maternal diabetes from the time of conception and throughout pregnancy (321–324).

Type 2 diabetes is occurring with increasing frequency in women of reproductive age, often in association with obesity. Although less well studied, infants of mothers with type 2 diabetes appear to have increased risks of similar kinds of malformations and other complications of pregnancy as infants of mothers with type 1 diabetes (324–327).

There is controversy over whether women with gestational diabetes also are at increased risk to have children with malformations. When maternal diabetes does not develop until after the first trimester of pregnancy, an effect on embryogenesis would seem unlikely. However, some women with gestational diabetes have unusually high blood glucose levels at the time of diagnosis and may actually have preexisting abnormalities of glucose metabolism. The infants of such women may be more likely to have malformations of the types seen in children of mothers with preexisting type 1 diabetes (328–330).

**36.3.3.5.3 Phenylketonuria.** About 75–90% of children of women with PKU who are not adequately treated during pregnancy are intellectually disabled and microcephalic (331,332). These children may also have prenatal growth retardation, congenital heart disease, and an appearance that is reminiscent of fetal alcohol syndrome. Children of women with PKU are usually heterozygous carriers and do not have PKU themselves. Children are damaged during gestation by exposure to very high levels of phenylalanine, phenylpyruvic acid, and other potentially toxic metabolites in the maternal blood (332).

Effective treatment of the mother beginning before conception and continuing throughout pregnancy reduces the risk substantially (332,333). It is extremely important to ensure that all females with PKU receive this information before and during their reproductive years. Unfortunately, adult women with undiagnosed PKU have occasionally been identified after they have become pregnant (334,335). A few of these women have

near-normal intelligence; others present with major psychotic disorders or have milder degrees of intellectual deficit than is commonly associated with classical PKU. Such women may come to attention only through the birth of an abnormal child. Thus, maternal screening for PKU subsequent to the birth of a child with the above-described abnormalities is one way of preventing the birth of additional affected children.

**36.3.3.5.4 Obesity.** Obesity is usually defined in relationship to height as the body mass index ( $\text{BMI} = \text{weight in kilograms}/(\text{height in meters})^2$ ). A BMI in the range of 25.0–29.9 is conventionally considered to indicate overweight; a BMI greater than 30.0, to indicate obesity. The overall frequency of major congenital anomalies was significantly correlated with the mother's prepregnancy BMI in the Collaborative Perinatal Project (336,337). An association of maternal obesity with congenital anomalies among the infants was also found in a record linkage study of 41,013 singleton pregnancies (338).

Several epidemiological studies have found that the risk of neural tube defects is almost doubled among infants of obese mothers (339). The results of studies of congenital heart defects, cleft palate, or cleft lip and palate among the infants of obese women are more heterogeneous, but most studies show a weak association (339). Associations of maternal obesity with hydrocephalus, anorectal atresia, diaphragmatic hernia, omphalocele, and hypospadias have also been reported, although these conditions are less well studied.

**36.3.3.6 Autoimmune and Isoimmune Disease.** Rh hemolytic disease, which results from transplacental transfer of maternal antibodies reactive against fetal red blood cells, has been recognized as a cause of hydrops fetalis for more than 70 years. Isoimmunization of an Rh<sup>-</sup> woman usually occurs during pregnancy by fetomaternal hemorrhage; amniocentesis or chorionic CVS may be a predisposing factor. Sensitization of the mother, and thus Rh hemolytic disease in the fetus in subsequent pregnancies, can largely be prevented by appropriate administration of Rh immunoglobulin (340,341) (see Chapter 74).

Fetal and neonatal disease may also be caused by transplacental transmission of various other maternal antibodies. Examples include Graves disease (342), idiopathic thrombocytopenia purpura (343,344), and systemic lupus erythematosus (345). Although exposure to these maternal antibodies stops at the time of delivery, permanent damage to relevant organs or tissues may occur in the fetus. For example, maternal anti-Ro/La antibodies can cause permanent heart block in an infant (346,347), fetal isoimmune thrombocytopenia can produce cerebral infarction and consequent porencephaly (348), and maternal antiacetylcholine receptor antibodies associated with myasthenia gravis can cause arthrogryposis in a child (349). A particularly interesting but poorly understood association exists between maternal systemic lupus erythematosus and the occurrence

of chondrodysplasia punctata in the infant (350). Fortunately, all these occurrences are rare.

### 36.4 PATERNAL EXPOSURES AND MATERNAL EXPOSURES BEFORE OR SHORTLY AFTER CONCEPTION

Concern is often voiced about the potential role of paternal exposures to toxic agents in the pathogenesis of birth defects (351). However, it seems unlikely that such paternal exposures could produce birth defects in a subsequent child except by germ cell mutation or alteration in the pattern of imprinting (352–354). Although these possibilities certainly exist for many agents to which fathers might potentially be exposed, the overall risk would presumably apply to many different genetic loci, and one would not expect to see any consistent pattern of abnormalities among the offspring of an exposed male. Rather, a low-frequency increase in a variety of disorders resulting from new autosomal dominant or chromosomal mutations or from altered imprinting would be anticipated.

No paternal exposure to any chemical or physical agent, including a number of known mutagens, has been convincingly shown to increase the risk of birth defects in subsequently conceived children (355). Germ cell mutations do occur, but their contribution to the burden of malformations appears to be too small to measure in comparison to the background risk. Paternal mutagenic exposures may contribute to infertility or early miscarriage and may be of importance from a population perspective, especially when considered over many generations. However, an individual couple concerned about exposure of the father to a potentially teratogenic or mutagenic agent can be reassured that such exposures probably present minimal risk to the fetus if they occur before conception and none at all if they occur postconceptionally.

Similar advice can be provided to women who were exposed to radiation or mutagenic chemicals, such as many cancer therapeutic agents, before conception. Available evidence indicates that the risk of congenital anomalies is not measurably increased among the children of women who have had preconceptional exposures in comparison to unexposed women (103,356).

The first two weeks after conception—the time between creation of the zygote and formation of the third germ layer, which marks the beginning of the embryonic period—is sometimes characterized as the “all-or-none period” with respect to teratogenic risk. Adverse environmental exposures that occur during this time are usually thought to either kill the conceptus, with loss of the pregnancy before it is recognized, or produce no permanent adverse effect because the multipotent cells that are present at this stage replace other cells that have been damaged or lost. The concept of the all-or-none period was developed on the basis of animal experiments that

showed lack of sensitivity to the teratogenic effects of ionizing radiation during this earliest phase of pregnancy (108).

Although many subsequent studies support the idea that embryogenesis proper is a time of greater susceptibility to teratogenic effects, it is now clear that some congenital anomalies may be induced during the cleavage, blastocyst, or bilaminar disk phases of development. The most compelling evidence for this comes from studies of mice exposed very early in pregnancy to several mutagenic chemicals (357) and studies of human infants who were conceived by in vitro fertilization. Alterations of imprinting are thought to be responsible for the increased risks of birth defects such as Prader–Willi syndrome and Silver–Russell syndrome that have been associated with in vitro fertilization in humans (358,359).

### 36.5 CONCLUSION

The need for reliable information on potentially teratogenic agents is likely to increase as a result of new technologies. One outcome of the Human Genome Project is a rapidly expanding capability to identify molecular targets for new therapeutic agents. However, in addition to mediating disease processes in adults, these targets may also be involved in morphogenesis or other critical functions in the embryo or fetus. Thus, in some cases the use of these agents in women who are pregnant or who become pregnant during therapy may pose specific and substantial risks for fetal development. The teratogenic potential of such agents will, therefore, be an especially important consideration.

Nanotechnologies (molecular level devices or interventions) are being developed for both diagnostic and therapeutic purposes. Very little is known about the risks of human exposures to such agents at present, and nothing is known about their possible effects on embryonic and fetal development.

Our recognition of epigenetic mechanisms (e.g. imprinting) that may modify gene expression and may also create transgenerational consequences opens new possibilities that will need to be considered in terms of risk assessment. These concerns may be especially important in the context of in vitro fertilization, intracytoplasmic sperm injection, and other assisted reproductive technologies that may bypass normal epigenetic control mechanisms that operate around the time of conception.

These new concerns are superimposed on our limited knowledge of the teratogenic effects of existing therapeutic, environmental, and dietary agents. There is an urgent need to develop approaches to screening for risks related to such mechanisms and for the appropriate evaluation of human exposures.

In conclusion, a wide variety of potentially teratogenic exposures may be encountered during pregnancy. Insufficient evidence is available for the complete characterization of most such exposures, and further information in this area is badly needed. At present, emphasis should be placed on

the avoidance of potentially hazardous agents unless benefits to the mother or infant from the proposed exposure clearly outweigh the hazards to the fetus. Well-informed women, supported by knowledgeable and sensitive health care providers, form one of the strongest lines of defense for the fetus against potentially hazardous exposures.

## Biographies

**Jan M. Friedman, MD, PhD, FAAP, FABMG, FCCMG, FRCPC**, received his MD and MS degrees from the Tulane University in New Orleans and his PhD in Genetics from the University of Washington in Seattle. He completed a residency in Pediatrics at Chicago Children's Memorial Hospital and a clinical fellowship in Medical Genetics at the University of Washington. He is certified by the American Board of Pediatrics, the American Board of Medical Genetics, the Canadian College of Medical Geneticists, and the Royal College of Physicians and Surgeons of Canada.

Dr Friedman is a professor of Medical Genetics at the University of British Columbia. From 1989–1999, he served as the head of this department. He is currently Acting Executive Director of the Child & Family Research Institute and Acting Associate Dean (Research) in the UBC Faculty of Medicine.

Dr Friedman is an author of more than 225 articles and 8 books. He has served as president of the Teratology Society, Founding President of the Association of Professors of Human Genetics, President of the Canadian College of Medical Geneticists, Treasurer of the American Society of Human Genetics, and member of the Advisory Board of the CIHR Institute of Genetics.

Dr Friedman's honors include the receipt of awards for excellence in both clinical and basic science teaching from the UBC Department of Medical Genetics, the UBC Killam Teaching Award, the Thomas Shepard Lectureship of the Organization of Teratogen Information Specialists, The Robert L Brent Lectureship of the Teratology Society, The Bock Prize and Lectureship in Developmental Biology and Genetics of the Alfred I Dupont Hospital for Children, the Irene Uchida Lectureship at the University of Manitoba, the Joseph Warkany Lectureship of the Teratology Society, and the Terry Klassen Lectureship of the Women's & Children's Health Research Institute in Edmonton, Alberta.

Dr Friedman's current research focuses on the use of genomic technologies to identify causes of intellectual disability. He also studies the effects of various medications on human embryonic and fetal development and has made important contributions to the clinical and epidemiological understanding of neurofibromatosis.

**Dr James W. Hanson, MD** is the Director of the Center for Developmental Biology and Perinatal Medicine (CDBPM), at the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), NIH. He attended the Johns Hopkins University and subsequently received his Doctor of Medicine degree from the University of Iowa, College of Medicine. His residency in pediatrics was at the Johns Hopkins Hospital. He spent 2 years as a medical epidemiologist in the Birth Defects Section at the US Centers for Disease Control and Prevention in Atlanta, Georgia. From 1974 through 1976, he was a postdoctoral fellow in dysmorphology with Dr David Smith at the University of Washington. In 1976, he joined the Department of Pediatrics at the University of Iowa, and he became Director of the Division of Medical Genetics in 1977.

In 1991, Dr Hanson was a Joseph P Kennedy, Jr. Foundation Fellow in Public Policy, assigned to the US Senate Subcommittee on Disability Policy. Other subsequent federal roles include Senior Advisor for Provider Liaison to the National Vaccine Program Office, Office of the Assistant Secretary for Health; Special Assistant to the Director, Center for Research for Mothers and Children, NICHD; and Senior Advisor, Office of Policy Analysis, Office of the Administrator, Agency for Health Care Policy and Research (now AHRQ). He was detailed to the Office of Public Health and Science, DHHS, on policy issues related to the future of academic health centers. He was appointed to the position of Senior Advisor for Medical Genetics and Acting Chief of the Clinical and Genetic Epidemiology Research Branch, Genetics and Epidemiology Program, Division of Cancer Control and Population Sciences, NCI, in 1998, to develop a National Cancer Genetics Research Network. In 2002, he became Chief of the Mental Retardation and Developmental Disabilities Branch at NICHD. In 2003, he was appointed to his current position.

Dr Hanson's research interests include the effects of environmental agents on fetal growth and development, patterns of malformation and abnormal fetal development, newborn screening, prenatal screening, birth defects epidemiology, cancer genetics, information/communications technology, nanotechnology and point of care technologies, especially as they relate to public health and public policy aspects of genetics, preventive health care, and both domestic and international children's health policy issues. He has written numerous scientific articles and has been a member of the American Medical Association, the American Academy of Pediatrics, the American Pediatric Society, the Society for Pediatric Research, the American Society of Human Genetics, the American Public Health Association, the Great Plains Genetics Services Network, and the Iowa Medical Society. He is a Past-President of the Teratology Society. He is a founding fellow and was a founding member of the Board of Directors of the American College of Medical Genetics.

## Neurodevelopmental Disabilities: Global Developmental Delay, Intellectual Disability, and Autism

*John B Moeschler*

Section of Medical Genetics, Department of Pediatrics, Dartmouth Medical School  
and Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA

### 37.1 INTELLECTUAL DISABILITY AND GLOBAL DEVELOPMENTAL DELAY

Intellectual disability (ID) is a developmental disability presenting in infancy or the early childhood years though cannot be diagnosed until the child is older than approximately 5 years of age when standardized measures of developmental skills become reliable and valid. The American Association on Intellectual and Developmental Disability defines ID using measures of three domains: intelligence, adaptive behavior, and systems of supports afforded the individual (1). Thus, one cannot rely solely on the measure of IQ to define ID. The term “intellectual disability” largely has replaced “mental retardation,” at least in the United States (1). Often, it is solely intelligence (typically measured by an intelligence quotient (IQ)) that is used to characterize intellectual function in the medical literature; however, standardized measures of “adaptive behavior” and of “social supports” should be considered to provide a more comprehensive and reliable data set for describing a person. Such measures may affect the medical genetic evaluation process and outcomes. The psychology profession requires completion of all measures before one can establish the diagnosis of ID in an individual. The gradations of disability are not different with this change in language: borderline, mild, moderate, severe and profound.

For the purpose of this chapter, we define intellectual disability as a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social and practical adaptive skills. The disability originates before 18 years of age (1). The prevalence of ID is estimated to be between 1% and 3% (2). Costs (direct and indirect) to support individuals with ID are large, estimated to be approximately \$1M average lifetime costs per person (3).

It has been estimated that the lifetime costs for medical care of U.S. children born with an ID in 2000 will be \$50 billion (4).

### 37.2 GLOBAL DEVELOPMENTAL DELAY

The type of disability identified is an important preliminary step because the type influences somewhat the diagnostic investigation pathway. Global developmental delay (GDD) is defined as a significant delay in two or more developmental domains including gross or fine motor, speech/language, cognitive, social/personal, and activities of daily living and is thought to predict a future diagnosis of ID (5). Such delays require accurate documentation using norm-referenced and age-appropriate standardized measures of development administered by experienced developmental specialists. The term global developmental delay is usually reserved for younger children (typically <5 years of age). Children with GDDs are those who present with delays in the attainment of developmental milestones at the expected age; this implies deficits in learning and adaptation, which suggests that the delays are significant and predict later ID. However, delays in development, especially those that are mild, may be transient and lack predictive reliability for ID or other developmental disabilities. This requires the clinician to judge the significance of the presenting signs and symptoms and the likelihood that they imply a pathological problem and not a normal variation in development in the infant or very young child. This, in turn, will determine the optimal diagnostic evaluation pathway. The prevalence of GDD is estimated to be 1–3% (5–7).

The purpose of identifying the cause is to address treatment options, discuss the expected clinical course and offer information regarding risk of recurrences for the

family. For parents or family members, the motivations to understand the cause of the disability vary. For example, Lenhard et al. (8) assessed the psychological benefit of a diagnosis by comparing the level of anxiety, guilt, and emotional burden among three groups: mothers of nondisabled children, mothers of children with Down syndrome, and mothers of children with idiopathic ID. They reported that mothers of children with Down syndrome and nondisabled children had similar scores for these measures, whereas mothers of children with idiopathic ID had “broad psychoemotional disadvantages.” The authors offered the opinion that Down syndrome is well known such that mothers of affected children may have different experiences from mothers of children with ID of other causes.

Graungaard and Skov (9) interviewed parents of eight children aged 1–27 months who had recently been diagnosed with significant physical and mental disabilities and concluded that a diagnosis “could enable parents to regain predictability and control in their life” and provide them with active coping strategies.

Because “we do not know if the parents’ ability to adapt to and cope with their child’s ID is actually improved by knowing a specific genetic cause,” Makela et al. (10) set out to address this question and interviewed families in depth in an effort to address the “value” of a specific etiological diagnosis in the child with an ID. Their qualitative research involving interviews of families of children with ID with and without an etiologic diagnosis and found these 20 families had specific stated needs and feelings about what a diagnosis offers:

1. Validation. A diagnosis established that the problem (ID) was credible, which empowered them to advocate for their child.
2. Information. A diagnosis was felt to help guide expectations and management immediately, and provide hope for treatment or cure in future.
3. Procuring services. The diagnosis assisted families in obtaining desired services, particularly in schools.
4. Support. Families expressed the need for emotional companionship that a specific diagnosis (or “similar challenges”) assisted in accessing.
5. Need to know. Families widely differed in their “need to know” a specific diagnosis, ranging from strong to indifferent.
6. Prenatal testing. Families varied in their emotions, thoughts and actions regarding prenatal genetic diagnosis.

Families differ in the importance of the specific etiology of their family member’s disability and this may change with time (lessening as the child ages to adult (11)). The medical geneticist might be advised to explore the motivations with families as the evaluation process and treatment outcome are valued differently by families.

### 37.3 DEFINITION OF A DIAGNOSIS

There is no unanimity in the definition of a “genetic diagnosis.” For many families and physicians, the diagnosis of the neurodevelopmental disability (e.g. autism, mild ID, etc.) is a sufficient clinical diagnosis and it does not always lead to counseling the patient or family about the potential value of the etiological evaluation (7,10). Furthermore, there is neither shared definitions of “treatment” and “improved outcomes” resulting from a genetics evaluation, nor a body of literature demonstrating the value of a diagnosis in reference to the long-term outcome for those with neurodevelopmental disabilities. Nevertheless, expert opinion with support of many case series indicate that a comprehensive evaluation is required to plan health care for individuals with neurodevelopmental disorders (5,7,12–16).

Schaefer and Bodensteiner (13) wrote that a specific diagnosis is that which “can be translated into useful clinical information for the family, including providing information about prognosis, recurrence risks, and preferred modes of available therapy.” Van Karnebeek et al. (17) defined etiologic diagnosis as “sufficient literature evidence ... to make a causal relationship of the disorder with mental retardation likely, *and* if it met the Schaefer–Bodensteiner definition.”

This chapter defines the “genetic diagnosis” as that in which there is sufficient literature to make a causal inference between the clinical and laboratory diagnostic information and the patient’s phenotype and thus informing treatment options, recurrence risks and patient outcomes.

For some patients, the clinical diagnosis cannot be confirmed by genetic diagnostic testing—the clinical recognition of a well-known genetic syndrome (e.g. Cornelia de Lange syndrome) for which comprehensive genetic diagnostic testing is negative for the known mutations (18).

Furthermore, at this time in the history of the practice of medical genetics and given the advances in exome and genome sequencing, the approach in the clinic to an individual patient is about to experience a sea-change from “phenotyping” the patient to determine which test should be ordered toward interpreting genomes and applying focused phenotyping based on that sequence result (19–21). Nevertheless, for the time being, the clinical approach to the patient with neurodevelopmental disability will continue to be in the tradition of the profession to include these elements: the child medical history (including prenatal and birth histories); the family history, which includes construction and analysis of a pedigree of three generations or more; the physical and neurologic examinations emphasizing the examination for minor anomalies (the “dysmorphology exam”); and, the examination for neurologic or behavioral signs that might suggest a specific recognizable syndrome or diagnosis. After the clinical genetic evaluation, judicious use of the laboratory tests, imaging, and other consultants based on best evidence are important in establishing the diagnosis (Table 37-1).

**TABLE 37-1** The Medical Genetics Evaluation for Global Developmental Delays or ID

## Medical Genetics Evaluation Process:

1. Clinical history
2. Family history
3. Physical examination (especially for minor anomalies)
4. Neurological examination
5. Specific confirmatory genetic tests for suspected syndromes
6. Microarray CGH
7. Fragile X molecular genetic testing
8. Metabolic screening in all<sup>a</sup>
9. Targeted MRI brain imaging

<sup>a</sup>See Table 37-5.

Adapted from Moeschler et al. (7), Moeschler (82), Michelson et al. (77), and Van Karnebeek and Stockler (80).

The medical geneticist experienced in the diagnostic evaluation and treatment of patients with neurodevelopmental remains the essential element in the evaluation process. This expert must be facile with the dysmorphology examination (and morphological pattern recognition) as well as the standard neurological examination. Recently, an international group of clinicians expert in the field of dysmorphology has published a proposed nomenclature to be used to describe human morphology (22). This effort is designed to improve the description of patient phenotype and facilitate comparison of findings among patients. It also serves to bring consistency and precision needed for communicating with colleagues in the research community. Pattern recognition of minor morphologic abnormalities (i.e. “dysmorphology” (23)) remains a pivotal skill of the medical geneticist in the evaluation of the patient with neurodevelopmental disability. Currently, the recognition of the pattern of dysmorphology, when present in the patient with neurodevelopmental disability, facilitates the efficient diagnostic evaluation process.

### 37.4 GENETIC MECHANISMS OF ID

The number of genes identified that cause ID suggests that an ID phenotype can emerge as the final common pathway of many different types of abnormal cellular processing and that no one overriding mechanism is likely to be the cause of intellectual (24). There are over 2500 genes or phenotypes listed in OMIM with “mental retardation” as the search term, and it is estimated that one-third of the entire genome is expressed in the human brain. Mutations in more than 450 genes have been identified to cause intellectual disabilities and related cognitive disorders (25). There are more than 200 X-linked genes for ID cloned or mapped (15). There are many inferred mechanisms by which pathogenic mutations affect CNS function, i.e. cause ID. It is emerging that ID can result from a wide range of protein abnormalities.

The genes identified at the earliest were frequently signaling molecules in the RhoGTPase pathway (*GDI*, *PAK3*, *ARHGEF6*) or associated with chromatin remodeling (*RPS6KA3*, *ATRX*). Most recently, components of the synaptic vesicle or components necessary for its formation have been identified as defective (*SYN1*, *SLC6A8*, *NLGN4* and *DLG3*) and a number of novel transcription factors (*ZNF41*, 81 and 674) have been found. Inlow and Restifo (26) identified the following categories of mechanism or dysfunction by an in silico review: enzymatic, mediators of signal transduction, binding proteins, transporter proteins, cell adhesion molecules, structural molecules, motor proteins, tRNAs, apoptosis regulators, chaperones, and enzyme regulators. There are at least two curated online resources for X-linked genes causing ID: <http://xlmr.interfree.it/home.htm> and [http://www.ggc.org/xlmr\\_update.htm](http://www.ggc.org/xlmr_update.htm).

### 37.5 DIAGNOSTIC TESTING OF PATIENTS WITH ID OF UNKNOWN CAUSE

Often, the expert medical geneticist or other specialist will recognize the likely or certain cause of the ID upon complete of the history and examination (27). More often, the cause of the disability is not certain and calls for a stepwise diagnostic evaluation with laboratory, imaging and consultations with other expert clinicians.

#### 37.5.1 Cytogenomic Copy Number Abnormalities

Advances in molecular genetic technology have quickened the pace of the discovery of the genetic underpinnings of disorders. DNA and RNA arrays now enable the detection of deletions, duplications and reduced expression of candidate genes. This applies to those with ID and/or autism spectrum disorders (ASDs). The clinical application of the chromosomal microarray has replaced the standard karyotype, with certain clinical exceptions (such as in use of the standard karyotype for confirming common syndromes such as Down syndrome) (28). There are also recognizably syndromes associated with chromosomal abnormalities that are detectable by conventional karyotyping or by targeted fluorescent in situ hybridization (FISH) analysis based on suspicion of the specific syndrome, such as Prader–Willi and Angelman syndrome (15q11.2–q13), Williams–Beuren syndrome (7q11.23), Smith–Magenis syndrome (17p11.2), DiGeorge syndrome (22q11.2), and monosomy of 1p36.1. Some balanced chromosomal translocations, not detectable by microarray, may be causal of the ID by mechanisms such as position effects (29).

Nevertheless, the cytogenomic microarray is more sensitive than the standard karyotype at identifying genomic imbalance as the cause of ID or ASDs. The

types of clinical laboratory microarrays vary somewhat (28) and there is little published data with head-to-head comparison of test performance by array type (30). The published diagnostic rates among study populations with ID range from 5 to 20%, about twice the rate by conventional karyotype (28,31–33). Most of these cases are microdeletion/duplications with many recurrent patients with similar recognizable phenotypes (Table 37-2 taken from Vissers et al. (33)). The pathogenic mechanisms for these deletions or duplications are challenging to predict, i.e. whether a syndrome is due to a mutation in a single gene or the result of deletion, duplication or dysregulation of multiple genes. For example, application of microarray to known syndromes, similar to CHARGE syndrome, has allowed for identification of haploinsufficiency of a single gene as cause for this known syndrome (see Table 37-3 for a list of others). Many of the microdeletions/duplications are rare or unique. As a consequence, there are several efforts to catalog patient phenotypes associated with copy number abnormalities (28,34,35). Table 37-3 provides a partial listing of prevalent genes by proposed mechanism.

Cytogenomic microarray studies may identify candidate genes for autosomal-dominant ID. Autosomal-recessive forms of ID are not well studied; much more is understood about X-linked genes causing disability. Only three different genes for autosomal-recessive ID have been identified thus far (36–38) including forms that are associated with microcephaly.

### 37.5.2 X-Linked ID

A number of factors have contributed to the progress in understanding ID due to X-linked genes, particularly when the pace of discovery is compared to that of autosomal genes (15). Some of these factors include longstanding awareness of the excess of males in many population studies dating to the nineteenth century; a large number of published clinical reports of large X-linked pedigrees dating back 70 years (39); the intense interest in fragile X syndrome (FXS) for some 40 years (40); and, the relative ease of mapping and identifying X-linked genes as compared to autosomal genes. More recently, advances in molecular genetic technology have quickened the pace of X-linked gene discovery, particularly the utilization of genes and genomic DNA in arrays has allowed for detection of deletions, duplications and reduced expression of candidate genes (41). Finally, advances in genome sequencing technology has made it possible for laboratories to sequence all X-linked genes in a single individual to identify pathogenic mutations (42).

Approximately 200 X-linked genes cause ID; about half have been identified and another 20% are regionally mapped. All genes responsible for X-linked intellectual disability (XLID) families reported before the rediscovery of FXS have now been identified; and, most, if not all, are the high-prevalence genes, that is, those

of a prevalence of 1% or greater. Nevertheless, there remain many genes unmapped and mapped yet unidentified and together they comprise a substantial proportion of XLID.

XLID often is subdivided into syndromic (S-XLID) and nonsyndromic (NS-XLID) forms, depending on whether further abnormalities are found on physical examination, laboratory investigation and brain imaging (15,43,44). Roughly two-thirds of XLMR cases are thought to be nonsyndromic (45); however, as the possibilities for classifying families through molecular studies improve, and as patients are examined in more detail, it is likely that the proportion of syndromic cases that are diagnosed will increase, with a concomitant decrease in the nonsyndromic cases. This is illustrated by the FXS, which was initially described as nonsyndromic and is now considered to be the most frequent example of S-XLMR. Moreover, mutations in several XLID genes can give rise to both nonsyndromic and syndromic forms, which demonstrates the difficulties in such classification schema.

### 37.5.3 Fragile X Syndrome

In 1969, Lubs (46) identified a family with four male members diagnosed with ID, each of whom had an unusual chromosomal gap on his X chromosome long arm, a “marker X chromosome” later confirmed by Sutherland et al. (47,48) to be related to certain cell culture conditions that render the chromosome “fragile.” The *FMR1* gene was cloned in 1991 (49) and in almost all cases, the causative mutation is the expansion of a CGG repeat located in the 5′ untranslated region (UTR) of *FMR1*. The length of the CGG repeat in the healthy population repeat is from 6 to 54 repeats (50). When the number of repeats exceeds 200, the expansion is referred to as a full mutation allele and results in FXS. At the molecular level, the large number of CGG repeats in the full mutation leads to marked methylation of both the CGG repeats and the *FMR1* promoter, hypoacetylation of associated histones, and chromatin condensation; these epigenetic changes result in transcriptional silencing of *FMR1* and subsequent loss of its protein product, fragile X mental retardation protein (FMRP) (51). Alleles with an intermediate number (55–200) of repeats are referred to as premutation alleles. Premutation alleles do not cause an FXS phenotype but are prone to large increases in repeat length during meiosis, especially female meiosis (50).

There are well-characterized clinical features in males with FXS that females, and rare males with a large expansion, may lack. Thus, it is recommended that any child who presents with developmental delay, borderline intellectual abilities, or ID, or has a diagnosis of autism without a specific etiology should undergo molecular testing for FXS (52). It is estimated that 2–6% of such patients will be found to have an *FMR1* mutation.

**TABLE 37-2 Recurrent Interstitial CMA Deletions and Duplications in ID**

Name	Size (Mb) <sup>a</sup>	LCR	MIM	Clinical Features
1q21.1 microdeletion	1.1	+	612474	Mild-to-moderate MR, MC, cardiac abnormalities, cataracts, clear incomplete penetrance
1q21.1 microduplication	1.1	+	612475	Autism or autistic behaviors, mild-to-moderate MR, microcephaly, mild FD
1q41q42 microdeletion	1.2	—	—	MR, seizures, various dysmorphisms, cleft palate, diaphragmatic hernia
2p15q16.1 microdeletion	3.9	—	—	MR, MC, receding forehead, ptosis, telecanthus, short palpebral fissures, downslanting palpebral fissures, broad/high nasal bridge, long/straight eyelashes, smooth and long philtrum, smooth upper vermilion border, everted lower lip, high narrow palate, hydronephrosis, optic nerve hypoplasia
3q29 microdeletion	1.6	+	609425	MR, mild FD, including high nasal bridge and short philtrum
3q29 microduplication	1.6	+	611936	Mild/moderate MR, MC, obesity
7q11.23 microduplication	1.5	+	609757	MR, speech and language delay, autism spectrum disorders, mild FD
9q22.3 microdeletion	6.5	—	—	MR, hyperactivity, overgrowth, trigonocephaly, macrocephaly, FD
12q14 microdeletion	3.4	—	—	Mild MR, failure to thrive, proportionate short stature and osteopoikilosis
14q11.2 microdeletion	0.4	—	—	MR, widely spaced eyes, short nose with flat nasal bridge, long philtrum, Cupid's bow of the upper lip, full lower lip, auricular anomalies
15q13.3 microdeletion	1.5	+	612001	MR, epilepsy, hypotonia, short stature, microcephaly and cardiac defects
15q24 microdeletion	1.7	+	—	MR, growth retardation, MC, digital abnormalities, genital abnormalities, hypospadias, loose connective tissue, high frontal hairline, broad medial eyebrows, downslanted palpebral fissures, long philtrum
16p11.2 microdeletion/duplication	0.6	+	611913	Association with MR, autism, schizophrenia
16p11.2p12.2 microdeletion	7.1	+	—	MR, flat facies, downslanting palpebral fissures, low-set and malformed ears, eye anomalies, orofacial clefting, heart defects, frequent ear infections, short stature, minor hand and foot anomalies, feeding difficulties, hypotonia
16p13.1 microduplication	1.6	+	—	Association with autism, significance uncertain
16p13.1 microdeletion	1.6	+	—	MR, MC, epilepsy, short stature, phenotypic variability
17p11.2 microduplication <sup>b</sup>	3.7	+	610883	MR, infantile hypotonia, failure to thrive, autistic features, sleep apnea, and structural cardiovascular anomalies
17q21.31 microdeletion	0.5	+	610443	MR, hypotonia, long hypotonic face with ptosis, large and low set ears, tubular or pear shaped nose with bulbous nasal tip, long columella with hypoplastic alae nasi, broad chin
19q13.11 microdeletion	0.7	—	—	MR, pre- and postnatal growth retardation, primary microcephaly, hypospadias, ectodermal dysplasia including scalp aplasia, dysplastic nails and dry skin
22q11.2 microduplication	3.7	+	608363	Highly variable. MR, FD, for example widely spaced eyes and downslanting palpebral fissures, velopharyngeal insufficiency, conotruncal heart disease
22q11.2 distal microdeletion	1.4–2.1	+	611867	MR, prematurity, prenatal/postnatal growth delay, mild skeletal abnormalities, arched eyebrows, deep set eyes, smooth philtrum, thin upper lip, hypoplastic alae nasi, small pointed chin
Xq28 microduplication	0.4–0.8	—	—	MR, severe hypotonia, progressive lower limb spasticity, absent or very limited speech

FD, facial dysmorphisms; LCR, low copy repeat; MC, microcephaly; MR, mental retardation.

### 37.5.4 Autism Spectrum Disorders

Autism is a pervasive developmental disorder involving deficits in three domains: social skills, communication, and repetitive behaviors or restricted interests, all before the age of 36 months (53). Typically, the behavioral and developmental symptoms are noted shortly

after age of 1 year and before the second birthday. The ASDs (54) include those with autism, pervasive developmental disorders—not otherwise specified, and Asperger syndrome.

There are several reports of a recent rise in prevalence of ASDs worldwide. Current estimates of prevalence for

From Vissers et al. (33).

all pervasive developmental disorders are in the range of 20–80 per 10,000 individuals (55–58). A review of studies completed between 1998 and 2001 from several countries concluded that the prevalence of autism is about 13 per 10,000 individuals and for pervasive developmental disorders more generally, 37 per 10,000 individuals (56). Examination of possible factors behind the rising reported incidence has led to one group to report that the incidence of autism rose seven to eightfold in California from the early 1990s through 2007. Quantitative analysis of the changes in diagnostic criteria, the inclusion of milder cases, and an earlier age at diagnosis during this period suggests that these factors probably contributed 2.2-, 1.56-, and 1.24-fold increases in autism, respectively, but cannot fully explain the magnitude of the rise in autism in California. Differential migration also likely played a minor role. Wider awareness, greater motivation of parents to seek services as a result of expanding treatment options, and increased funding may each have contributed, but documentation or quantification of these effects is lacking. Having demonstrated the challenges of documenting an incidence trends in ASDs, these authors concluded that “with no evidence of a leveling off, the possibility of a true increase in incidence deserves serious consideration” (59). If there is a biological or environmental explanation for the observed increased incidence of the diagnosis of ASDs, it is not yet known (60).

ASDs are four times more common in males than females (61). There is a strong genetic basis to ASDs as indicated by the recurrence risk in families, twin studies, and the cooccurrence with chromosomal disorders and rare genetic syndromes. More than 100 genes or genomic disorders are known to cause ASDs (62).

The clinical presentation of the child with an ASD overlaps that with GDD, particularly in the early

years. For example, in the Childhood Autism Risks from Genetics and the Environment Study (63), which recruits preschool children from the California administrative data system, 71% of those who meet criteria for autism on both the Autism Diagnostic Observation Schedule (ADOS) (64) and Autism Diagnostic Inventory-Revised (ADI-R) also met criteria for ID. Many with ASDs will “outgrow” a diagnosis of GDD or ID in large part because the ability of the professionals to measure abilities improves as a child ages (59). This overlap complicated the diagnostic decision-making by the medical specialist as well as the study of the genetic and metabolic causes of ASDs. For example, at least 103 specific genes and 44 genomic loci have been reported in patients with ASD or autistic behavior. These genes and loci have all been causally implicated in ID, indicating that these two neurodevelopmental disorders share common genetic bases (62).

The genetic architecture of ASDs is highly heterogeneous (65). About 10–20% of individuals with an ASD have an identified genetic etiology. Microscopically visible chromosomal alterations have been reported in about 5% of cases; the most frequent abnormalities are 15q11–q13 duplications, and 2q37, 22q11.2 and 22q13.3 deletions. ASDs can also be due to mutations of single genes involved in autosomal-dominant, autosomal-recessive and X-linked disorders. The most common single-gene mutation in ASDs is FXS (*FMR1*), present in about 2% of cases. Other monogenic disorders described in ASDs include tuberous sclerosis (*TSC1, TSC2*), neurofibromatosis (*NF1*), Angelman syndrome (*UBE3A*), Rett syndrome (*MECP2*) and *PTEN* mutations in patients with macrocephaly and autism (Table 37-4) (66). Rare mutations have been identified in synaptic genes,

**TABLE 37-4 Monogenic Causes of Intellectual Disability, by Mechanism**

Gene	Locus	Disorder/Phenotype	Function of Encoded Protein; Subcellular Localization <sup>a</sup>
<i>Genes Required for Neurogenesis</i>			
Microcephalin	MCPH1/8p22-pter	Microcephaly vera	Cell cycle control and DNA repair
CDK5RAP2	MCPH3/q34	Microcephaly vera	Mitotic spindle function in embryonic neuroblasts
ASPM	MCPH5/1q31	Microcephaly vera	Formation of mitotic spindle during mitosis and meiosis
CENPJ	13q12.2	Microcephaly vera	Localization to the spindle poles of mitotic cells
<i>Genes Required for Neuronal Migration</i>			
LIS1	17p13.3	Miller Dieker syndrome: type 1 lissencephaly, pachygyria, subcortical band heterotopia (double cortex)	Interacts with dynein and plays a role in several function, including nuclear migration and differentiation
DCX/Dcn	Xq22.3	Type 1 lissencephaly, pachygyria, subcortical band heterotopia (double cortex)	Microtubule-associated protein (MAP)
RELN	7q22	Lissencephaly with cerebellar hypoplasia	Extracellular matrix (ECM) molecule, reelin pathway
VLDLR	9p24	Lissencephaly with cerebellar hypoplasia	Low-density lipoprotein receptor, reelin pathway
POMT1	9q34	Walker–Warburg syndrome (also known as HARD syndrome <sup>b</sup> )	Protein <i>o</i> -mannosyltransferase 1 (glycosylation of alpha-dystroglycan)
POMT2	14q24.3	Walker–Warburg syndrome	Protein <i>o</i> -mannosyltransferase 2 (glycosylation of alpha-dystroglycan)
POMGnT1	1p34	Muscle–eye–brain disease (MEB)	Protein <i>o</i> -mannose beta-1,2-n-acetylglucosaminyltransferase
Fukutin	9q31	Fukuyama congenital muscular dystrophy (FCMD) with type 2 lissencephaly	Homology with glycoprotein-modifying enzymes (no biochemical activity has been reported)
FLNA	Xq28	Bilateral periventricular nodular heterotopia (BPNH)	Filamin-1 (actin cross-linking phosphoprotein)
<i>Genes Required for Cellular Processes Involved in Neuronal and Synaptic Functions</i>			
FMR1	Xq27	FXS (Facial anomalies with macro-orchidism)	mRNA-binding protein, role in mRNA translation; potential regulation by RhoGTPase pathways; postsynaptic localization
FGD1	Xp11.2	Aarskog–Scott syndrome (Facial, digital and genital anomalies)	RhoGEF protein (GTP exchange factor), activate Rac1 and Cdc42
PAK3	Xq21.3	Nonsyndromic XLMR	P21-activated kinase 3; effector of Rac1 and Cdc42
ARHGEF6	Xq26	Nonsyndromic XLMR	RhoGEF protein, integrin-mediated activation of Rac1 and Cdc42
OPHN1	Xq12	MR with cerebella and vermis hypoplasia	RhoGAP protein (negative control of RhoGTPases; stimulates GTPase activity of RhoA, Rac1 and Cdc42; pre- and post synaptic localization)
TM4SF2	Xq11	Nonsyndromic XLMR	Member of the tetraspanin family, integrin-mediated RhoGTPase pathway regulation
NLGN4	Xp22.3	Nonsyndromic XLMR, autism, Asperger syndrome	Member of the neuroligin family, role in synapse formation and activity; post synaptic localization
DLG3	Xq13.1	Nonsyndromic XLMR	Protein involved in postsynaptic density structures; postsynaptic localization
GDI <sub>1</sub>	Xq28	Nonsyndromic XLMR	Regulation of Rab4 and Rab5 activity, and of synaptic vesicle recycling; pre- and post synaptic localization
IL1RAPL	Xp22.1	Nonsyndromic XLMR	Potential involvement in exocytosis and ion channel activity
<i>Transcription Signaling Cascade, Remodeling and Transcription Factors</i>			
NF1	17q11	Neurofibromatosis type 1 (NF1); MR is present in 50% of NF1 cases	RasGAP function, involved in Ras/ERK/MAPK signaling transcription cascade; postsynaptic protein
RSK2	Xp22.2	Coffin–Lowry syndrome (facial and skeletal anomalies)	Serine–threonine protein kinase, phosphorylates CREB, involved in Ras/ERK/MAPK signaling cascade, present in the postsynaptic compartment
CDKL5	Xp22.2	Rett-like syndrome with infantile spasms	Serine–threonine kinase (STK9), interacts with MECP2, potential implication in chromatin remodeling
CBP	16p13.3	Rubinstein–Taybi syndrome (mental retardation, broad thumbs and toes, dysmorphic face)	CREB (cAMP response element-binding protein 1) binding protein; chromatin-remodeling factor involved in Ras/ERK/MAPK signaling cascade
EP300	22q13.1	Rubinstein–Taybi syndrome	Transcriptional coactivator similar to CBP, with potent histone acetyl transferase: chromatin-remodeling factor

**TABLE 37-4 Monogenic Causes of Intellectual Disability, by Mechanism—cont'd**

Gene	Locus	Disorder/Phenotype	Function of Encoded Protein; Subcellular Localization <sup>a</sup>
<i>XNP</i>	Xq13	Large spectrum of phenotypes including ATRX syndrome (microcephaly, facial dysmorphic face, skeletal anomalies and alpha-thalassemia)	Homology with DNA helicases of the SNF2/SWI2 family, chromatin-remodeling factor, regulation of gene expression
<i>MECP2</i>	Xq28	Rett syndrome (female-specific syndrome) and other phenotypes including nonsyndromic MR	Methy-CpG-binding protein 2; chromatin-remodeling factor, involved in a transcriptional silencer complex
<i>DNMT3B</i>	20q11.2	ICF syndrome: immune deficiency associated with centromeric instability, facial dysmorphism and MR	DNA methyltransferase 3B, involved in chromatin remodeling
<i>ARX</i>	Xp22.1	Large spectrum of MR phenotypes: XLAG (X-linked lissencephaly and abnormal genitalia); West syndrome, Partington syndrome; nonsyndromic MR	Transcription factor of the aristaless homeoprotein-related proteins family
<i>JARID1C</i>	Xp11.2	Spectrum of phenotypes: MR with microcephaly, short stature, epilepsy, facial anomalies and nonsyndromic MR	Transcription factor and chromatin remodeling
<i>FMR2</i>	Xq28	Nonsyndromic MR	Potential transcription factor
<i>SOX3</i>	Xq27	Isolated GH deficiency, short stature and MR	SRY-BOX 3: transcription factor
<i>PHF8</i>	Xp11.2	MR with cleft lip or palate	PHD zinc-finger protein, potential role in transcription
<i>ZNF41</i>	Xp11.2	Nonsyndromic MR	Potential transcription factor
<i>GTF2I</i>			
<i>GTF2RD1</i>	7q11.23	Williams syndrome	Transcription factors, potential regulator of c-Fos and immediate-early gene expression
<i>PHF6</i>	Xq26	Börjeson–Forssman–Lehmann syndrome (hypogonadism, obesity, facial anomalies, epilepsy)	Homeodomain-like transcription factor
<i>Other Genes Involved in MR</i>			
<i>RPSS12</i>	4q24	Nonsyndromic ARMR	Member of the trypsin-like serine protease family, enriched in the presynaptic compartment
<i>CRBN</i>	3p25	Nonsyndromic ARMR	ATP-dependent protease; regulation of mitochondrial energy metabolism
<i>CC2D1A</i>	19p13	Nonsyndromic ARMR	Unknown function, protein contains C2 and DM14 domains
<i>FTSJ1</i>	Xq11.2	Nonsyndromic XLMR	Role in tRNA modification and mRNA translation
<i>PQBP1</i>	Xq11.2	Large spectrum of MR phenotypes including nonsyndromic MR	Polyglutamine-binding protein, potentially involved in pre-mRNA splicing
<i>FACL4</i>	Xq22.3	Nonsyndromic XLMR	Fatty-acid synthase-CoA ligase 4; possible role in membrane synthesis and/or recycling
<i>SLC6A8</i>	Xq28	Creatine deficiency syndrome (MR with epilepsy and dysmorphic features) and nonsyndromic MR	Creatine transporter, role in homeostasis of creatine in the brain
<i>OCRL1</i>	Xq25	Lowe syndrome (MR, bilateral cataract and renal Fanconi syndrome)	Inositolpolyphosphate 5-phosphatase (central domain) and RHoGAP-like C-terminal domain
<i>AGTR2</i>	Xq24	Nonsyndromic XLMR	Angiotensin II receptor type 2, signaling pathway
<i>SLC16A2</i>	Xq13.2	Severe syndromic form MR with abnormal levels of thyroid hormones	Monocarbohydrate transporter, T3 transporter
<i>SMS</i>	Xp22.1	Snyder–Robinson syndrome (macrocephaly, scoliosis, dysmorphic features)	Spermin synthase, CNS development/function (neuron excitability)
<i>UBE3A</i>	15q11	Angelman syndrome	Ubiquitin–protein ligase E3A; protein degradation (proteasome): CNS development/function (neuron differentiation)

The table does not represent an exhaustive list of genes involved in MR disorders. For additional genes, see the review by Inlow and Restifo (26), and online resources: <http://xlmr.interfree.it/home.htm> and [http://www.ggc.org/xlmr\\_update.htm](http://www.ggc.org/xlmr_update.htm).

<sup>a</sup>Subcellular localization is indicated mainly for protein shown to be present in the pre- and/or postsynaptic compartments.

<sup>b</sup>HARD syndrome includes hydrocephalus (H), agyria (A), retinal dysplasia (RD), with or without encephalocele, often associated with congenital muscular dystrophies.

From Chelly et al. (83).

including *NLGN3*, *NLGN4X* (67), *SHANK3* (68), and *SHANK2* (69). Recent whole-genome microarray studies have revealed submicroscopic deletions and duplications, called copy number variation (CNV), affecting many loci and including de novo events in 5–10% of ASD cases (70–74).

### 37.5.5 Inborn Errors of Metabolism and ID

The inherited metabolic conditions that cause ID typically are associated with other neurological or systemic signs and symptoms. In several series of patients presenting with intellectual disabilities, the incidence of diagnosed metabolic disorders ranges from 1% or less to about 5% (75–79). While this incidence is lower than genomic or single-gene conditions, the potential for response to treatment is relatively better (80). In one systematic review of the literature (80), 81 inborn errors of metabolism (IEM) that were responsive to treatment and associated with ID were identified; of these, 50 were diagnosed with routine metabolic screening tests (Table 37-5): plasma amino acids, total serum homocysteine and acylcarnitine profile by tandem mass spectroscopy; urine organic acids, glycosaminoglycans, oligosaccharides, purines and pyrimidines, and creatine metabolites (Table 37-6). Several of the 81 identified to be associated with ID are detectable by routine newborn screening currently in place in the United States and around the world. Of those IEMs not identified by the metabolic tests listed in Table 37-5, the identification is based on clinical judgment and a “test-by-test strategy.” For 13 of these 81 IEMs that cause ID, whole-genome sequencing may be the best solution for diagnostic testing (80) (Table 37-7) because of difficulties with current diagnostic: a biomarker is not available or is unreliable and/or the test requires invasive testing, and/or the test is difficult to access (80).

### 37.5.6 CNS Malformations, ID and Brain Imaging

CNS malformations are a common finding in those with ID—abnormal findings on MRI are seen in approximately 30% of children with DD/ID. However, only in a fraction of these children does MRI lead to an etiologic or syndromic diagnosis.

Current recommendations range from performing brain images on all patients with DD/ID (14) to performing it only on those with indications on clinical examination, to being considered as a second-line investigation to be undertaken when features in addition to GDD are detected either on history or physical examination (81). The finding of a brain abnormality or anomaly on neuroimaging may lead to the recognition of a specific cause for an individual child’s DD/ID in the same way that a dysmorphic examination might lead to the inference of a particular clinical diagnosis. However, similar to other major or minor anomalies noted

<sup>a</sup>If phenotype/syndrome not indicated, there are only “nonsyndromic” families noted to date.

Modified from Bentacur (62).

on physical examination, abnormalities on neuroimaging typically are not sufficient for determining the cause of the DD/ID; the underlying precise, and presumably frequently genetic in origin, cause of the brain anomaly is often left unknown. Thus, although a CNS anomaly (often also called a “CNS dysgenesis”) is a useful finding, and indeed may be considered a useful “diagnosis.”

**TABLE 37-6 Routine Metabolic Screening Tests in Patients with ID or ASDs****Bargraph depicting the yield of 'Metabolic Screening Tests'**

Summary of all treatable IEM (n=50/62%) which can be detected by 'Metabolic Screening Tests', each of which is affordable and accessible with the potential to identify at least 2 IEM (and up to 22). Each bar represents the yield of the specific screening test, and lists the number and types of treatable IEM it can identify.

Coarse features, organomegaly	<ul style="list-style-type: none"> <li>Metabolic testing<sup>a</sup></li> </ul>

**TABLE 37-9 Primary Autosomal-Recessive Microcephaly Genes**

Gene	OMIM #	Percentage of Cases (%)	Citations
<i>MCPH1</i>	607117	<5	Jackson et al. (84)
<i>CDK5RAP2</i>	608201	<5	Bond et al. (85)
<i>ASPM</i>	605481	37–45	Bond et al. (37)
<i>CENPJ</i>	609279	<5	Bond et al. (85)
<i>STIL</i>	181590	<5	Kumar et al. (86)

It is, however, frequently not an etiologic or syndromic diagnosis in the usual sense of the term. This distinction is not always made in the literature on the utility of neuroimaging in the evaluation of children with DD/ID. The lack of a consistent use of this distinction has led to confusion regarding this particular issue.

Shevell et al. (5) reported a range of finding in their review. For example, in three studies totaling 329 children with developmental delay in which CT was used in almost all patients, and MRI was used in but a small sample, a specific cause was determined in 27–32% of

the children. In their systematic review of the literature, van Karnebeek et al. (17) reported nine studies on the use of MRI in children with ID. The mean rate of abnormalities found was 30%, with a range of 6.2% to 48.7%. These investigators noted that more abnormalities were found in children with moderate to profound ID versus those with borderline to mild ID (mean yield of 30% and 21.2%, respectively). These authors also noted that none of the studies reported on the value of the absence of any neurologic abnormality for a diagnostic work-up and concluded that “the value for finding abnormalities or the absence of abnormalities must be higher” than the 30% mean rate implied.

If neuroimaging is performed in only selected cases, such as those children with an abnormal head circumference or an abnormal focal neurologic finding, the rate of abnormalities detected is increased further than when utilized on a screening basis in children with a normal neurologic examination except for that the documentation of developmental delay.

Brain imaging is often useful in guiding the etiological investigations based on the specific CNS abnormalities noted on imaging. To illustrate just two examples,

**TABLE 37-10 Selected Syndromes with Agenesis of Corpus Callosum**

Syndrome	OMIM #	Gene(s)	Phenotype
Chondrodysplasia punctata 2, XL type	302960	<i>EBP</i>	Increased concentration of 8(9)-cholesterol, & 8-dehydrocholesterol
Donnai–Barrow s.	222448	<i>LRP2</i>	Hypertelorism, ocular coloboma, diaphragmatic hernia
Fumarate hydratase deficiency	136850	<i>FH</i>	Isolated increased concentration of fumaric acid on urine organic acid analysis
L1 syndrome	308840	<i>L1CAM</i>	Hydrocephaly, spasticity, adducted thumbs
Mowat–Wilson s.	235730	<i>ZEB2</i>	Distinctive facial features, Hirschsprung disease
Aicardi s.	304050	?	Chorioretinal lacunae, infantile spasms
Hereditary motor and sensory neuropathy with agenesis of corpus callosum	218000	<i>SLC12A6</i>	Mild to severe ID
Kallman s.	300836, 136350, 607123, 607002, 605806, 600483	<i>KAL1, FGFR1, PROKR2, PROK2, CHD7, and FGF8</i>	Anosmia, GnRH deficiency
X-linked Opitz/BBB syndrome	300000	<i>MID1</i>	Hypertelorism, hypospadias
Tetra-Amelia s.	273395	<i>WNT3</i>	Absence of all four limbs
Oro–facial–digital syndrome, type 3		<i>OFD1</i>	Cleft palate, lobed tongue, polydactyly, syndactyly

findings such as microcephaly (Tables 37-8 and 37-9) or agenesis of the corpus callosum (Table 37-10) can often lead to a specific genetic diagnosis.

### 37.6 SUMMARY

The developmental disabilities discussed in this chapter—ID and autism—are important public health problems. The accurate etiologic diagnosis provides the opportunity to improve health outcomes and quality of life as well as save health and social services costs. These are extremely heterogeneous conditions with varied responses to treatment. The specialist is able to provide the proper diagnostic approach for individual patients and families. In the near future, whole-genome sequencing may obviate the test-by-test approach of such expert clinicians and move the field of medical genetics to clarification of individual phenotypic variation and natural history as well as to personalize the treatment plans for such patients.

### Biography

**John B Moeschler** is a professor of Pediatrics, Dartmouth Medical School and director of the Division of Medical Genetics at Dartmouth–Hitchcock Medical Center. His research interest is in the clinical description and delineation of genetic syndromes, birth defects and developmental disabilities; genotype–phenotype correlations; and the natural history of such conditions. His research has been in collaboration with those in many other disciplines including molecular genetics and genomics and genetic epidemiology. His research interest became focused on genetic aspects of neurodevelopmental disabilities in 1978 during a fellowship in developmental disabilities at the University of Washington. In 2005, he received his Master of Science degree from The Dartmouth Institute for Health Policy and Clinical Practice. This study stimulated his other research interest, health care services research, particularly in those factors that improve health and health care for those with genetic conditions.

### 38.1 INTRODUCTION

Normal stature varies widely among ethnic groups, and also varies within each ethnic group, approximating a normal distribution. Short stature and tall stature are therefore relative terms and related to a person's ethnic, familial, and nutritional status. Before beginning a complex diagnostic evaluation or contemplating growth-promoting or growth-limiting therapy, one must be able to differentiate between pathologic short or tall stature and normal variants at each end of the normal range. Utilizing standardized growth curves allows for such differentiation. However, growth curves must be appropriate for the individual's genetic and ethnic background. In addition, allowances must be made for parental height, nutritional background, and the impact of chronic disease before an individual can be declared pathologically short or tall. One must also rule out constitutional delay or acceleration of maturation by correlating bone age and height. This normal variation in the timing of growth accounts for a large proportion of children referred for variations in growth. Adult height is a classic polygenic trait, influenced by genetic variants in at least 180 loci (1).

### 38.2 PATHOLOGIC SHORT STATURE

When it is established that a person is truly short for his or her genetic background, and does not simply have constitutional delay, the exact cause of the pathologic short stature must be delineated. If possible, it is essential that

a specific diagnosis be made because there are literally hundreds of causes of short stature that have differing prognoses, complications, and responses to treatments. A specific diagnosis is essential to provide appropriate treatment and accurate genetic counseling. The first step in the clinical evaluation of short stature is to determine whether the body habitus is proportionate or disproportionate (Figure 38-1). Children with disproportionate short stature usually have a skeletal dysplasia or metabolic bone disease (see Chapter 158), while those with proportionate short stature may have a more generalized disorder (i.e. malnutrition, chronic disease, psychosocial dwarfism, endocrine disorder, genetic syndrome, or chromosomal or teratogenic disorder, as discussed in Chapters 36, 43–45, and 83). Exceptions to this rule occur, and disproportionate dwarfism may occur in cases of severe cretinism, while proportionate shortening may occur in persons with osteogenesis imperfecta.

A mildly disproportionate body habitus may not be apparent on casual examination, and anthropometric measurements such as sitting height, upper/lower segment ratio, and/or arm span must be made before a relatively mild skeletal dysplasia (2) can be excluded. Once a person with short stature is found to be proportionate, it is helpful to determine whether the growth deficiency was of prenatal or postnatal-onset. Prenatal-onset growth deficiency usually implicates a fetal environmental insult or a generalized cellular genetic defect that may limit cellular mitosis.

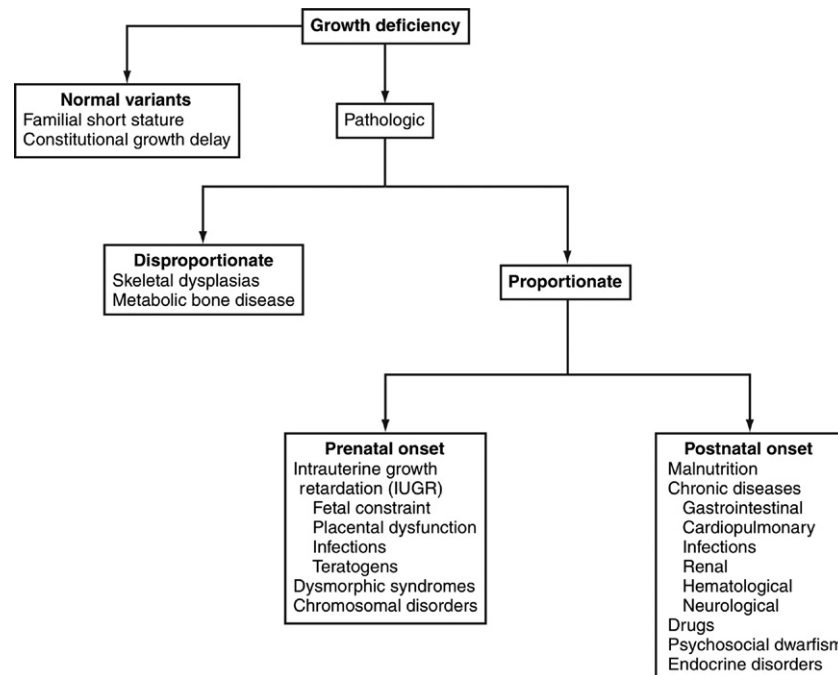

FIGURE 38-1 Classification of short stature.

Late fetal insults are more likely to demonstrate catch-up growth after birth when compared with environmental factors, which have an early impact in fetal life (3). On the other hand, postnatal-onset of proportionate growth deficiency usually implicates a postnatal environmental insult, such as infection, chronic disease, malnutrition, or an endocrine, psychological, or malabsorption disorder. These generalizations hold true whether or not the cause of the short stature is a single-system disorder, such as growth hormone deficiency or diabetes mellitus, or the short stature is associated with other abnormalities in a complex syndrome.

### 38.2.1 Proportionate Short Stature of Prenatal-Onset

Prenatal growth deficiency or intrauterine growth retardation (IUGR) can be due to numerous causes, both genetic and acquired. Mechanical late gestational constraint has been emphasized as the most common cause of prenatal growth deficiency (3). Most commonly, such small babies are born to small mothers with fathers of normal size, and they readily catch-up into the normal range within the first few months of postnatal life. Late fetal causes of growth deficiency, such as preeclampsia or placental insufficiency, usually show prompt resolution with postnatal catch-up growth. However, infants with disorders that adversely affect growth from early fetal life, such as chronic maternal hypertension, maternal diabetes mellitus with vascular changes, and heavy maternal smoking, may not show catch-up growth during the first six months of postnatal life. These conditions may result in diminished maternal blood flow to the placenta.

There are a wide variety of fetal malformation syndromes caused by single gene disorders, chromosomal

disorders, teratogens, or in utero infections in which fetal hypoplasia is part of the overall disorder (4,5) (Table 38-1). Infants with such malformation syndromes would not be expected to show catch-up growth, and some of these disorders can be associated with a high degree of perinatal lethality. Although etiologically heterogeneous, small size at birth may be associated with infant, childhood, and adult health implications (6–8). Long-term follow-up of over 1000 adults who were born small for gestational age (SGA) at term with no congenital abnormalities demonstrated small but significant deficits in academic achievement, with teachers less likely to rate them in the top 15th percentile of the class at age 16 years and more likely to recommend special education (9).

At age 26 years, those who had been born SGA were less likely to have professional or managerial jobs, with significantly lower levels of weekly income. Those born SGA with a small head size at age 5 years had substantially lower rates of professional attainment than those born SGA who had a normal head size at age 5 years. Also, adults born SGA had significant adult height deficits of approximately 5 cm (9). These findings have provided a rationale for treating infants with growth hormone, who were born SGA and did not catch-up in size by age 2 years (10). It is unknown if the lower rates of professional attainment in adults born SGA is due to their shorter stature or the underlying cause for their intrauterine growth deficiency, such as fetal alcohol syndrome, which would clearly impact both head size and professional attainment.

**38.2.1.1 Syndromic Disorders.** When the onset of growth deficiency is prenatal, one must differentiate between the numerous forms of intrauterine growth restriction (IUGR,

TABLE 38-1 Prenatal-Onset Growth Deficiency Disorders

Disorder	Key Clinical Findings		
Teratogenic disorders			
Fetal alcohol effects	Microcephaly, thin smooth philtrum, short palpebral fissures		
Fetal hydantoin effects	Ocular hypertelorism, hypoplastic nails, short nose		
Fetal trimethadione effects	Arched eyebrows, cupped helix, heart defects		
Fetal warfarin effects	Hypoplastic nose, stippled epiphyses, short limbs		
Fetal rubella effects	Deafness, cataracts, patent ductus arteriosus		
Fetal varicella effects	Cicatricial skin defects, limb hypoplasia, mental deficiency, seizures		
Maternal phenylketonuria effects	Microcephaly, cardiac defects, mental deficiency		
Chromosome Abnormalities			
Trisomy 18	Clenched hands, short sternum, low arch dermatoglyphic pattern		
Trisomy 13	Scalp defects, polydactyly, holoprosencephaly facies		
Triploidy	3-4 Syndactyly, dysplastic calvaria, cystic placenta		
4p syndrome	Ocular hypertelorism, hypospadias, preauricular pits		
5p syndrome	Cat-like cry, microcephaly, down-slanted palpebral fissures		
13q syndrome	Central nervous system defects, short thumbs, anal anomalies		
18p syndrome	Ptosis, protruding ears, mental deficiency		
18q syndrome	Prominent antihelix, midface hypoplasia, long palms		
45,X (Turner) syndrome	Lymphedema of hands and feet, webbed neck, broad chest with wide-set nipples		
Proportionate syndromes			
Disorder	Key Clinical Findings	Inheritance	Gene Testing
Brachmann–de Lange (122470)	Microcephaly, synophrys, thin downturned upper lip, small widely spaced teeth, micromelia, hirsutism, autistic tendencies, MR (IQ 30–102), occasionally with cardiac septal defects, hearing loss, myopia, gastrointestinal dysfunction, hypoplastic genitalia/cryptorchidism (99)	Sporadic, autosomal dominant X-linked (fewer than 1 percent pts have an affected parent)	3 genes encoding components of the Cohesin Complex: <i>NIPBL</i> (Nipped B-like) at 5p13.1 (100) <i>SMC1A</i> (segregation of mitotic chromosomes 1) gene at Xp11.22 (101) <i>SMC3</i> at 10q25
Rubinstein–Taybi (180849)	Normal prenatal growth with slowing of growth (height, weight and head circumference) in first few months of life, broad thumbs and halluces, down-slanted palpebral fissures, “Beaked nose” with prominent nasal septum, high arched palate, grimacing smile and talon cusp, moderate to severe mental retardation (IQ from 25 to 79), childhood/adolescent obesity. Variable features: cataracts, colobomas, congenital renal or cardiac defects, cryptorchidism (102)	Sporadic, autosomal dominant	<i>CREBBP</i> ( <i>Creb-binding protein</i> ) 16p13.3 (103) <i>EP300</i> at 22q13 (104)
Russell–Silver (180860)	IUGR with persistent postnatal growth deficiency, triangular face, normal-sized cranium, incurved (clinodactyly) 5th fingers, asymmetric limb length (may lead to decreased growth on the affected side with hemihypertrophy), risk of motor and cognitive developmental delay with learning disabilities (20)	Sporadic heterogeneous	10%—maternal disomy for 7p11.2 11p15 region: <i>H19</i> —maternal (105) <i>IGF2</i> gene (106)
Dubowitz (223370)	IUGR with postnatal growth deficiency, microcephaly with a high or sloping forehead and a broad and flat nasal bridge, flat or shallow supraorbital ridges, ptosis and blepharophimosis, with scarce lateral eyebrows, eczema, normal intelligence to mild to moderate MR, behavioral problems including hyperactivity (ADHD). Clinodactyly of the 5th fingers, and cutaneous syndactyly of the 2nd and 3rd toes. Genitourinary abnormalities may include hypospadias and cryptorchidism (107)	Autosomal recessive	<i>NSUN2</i> at 5p15.31 (107)

Continued

**TABLE 38-1 Prenatal-Onset Growth Deficiency Disorders—Cont'd**

Disorder	Key Clinical Findings	Inheritance	Gene Testing
Bloom (210900)	Microcephaly, malar erythema/sun sensitivity/telangiectasia, malar hypoplasia, Gastrointestinal Reflux (possibly contributing to infections of lung, middle ear and upper respiratory tract), sparse subcutaneous fat through infancy and early childhood, normal intelligence with poorly defined learning disability, early susceptibility to medical complications such as obstructive pulmonary disease, diabetes mellitus, and various cancers (12)	Autosomal recessive	<i>BLM</i> (DNA Helicase) at 15q26.1 (108) (quadriradial (Qr) in cultured blood lymphocytes and/or increased sister chromatid exchanges (SCEs) in any type of cultured cells)
Fanconi pancytopenia (227650)	Radial hypoplasia, hypoplastic thumbs, hyperpigmentation, pancytopenia (progressive bone marrow failure), increased risk of malignancy-acute myelogenous leukemia or myelodysplastic syndrome and solid tumors) (109). May have malformations of the kidneys/urinary tract, heart, GI system, oral cavity, CNS, ears (including hearing loss), developmental delay.	Autosomal recessive (110) Except <i>FANCB</i> mutations X-linked inheritance	Diagnostic test is detection of DNA aberrations when exposed to dipoxybutane (DEB) or mitomycin C (MMC) 15 Genes in the FA complementation group (111) ( <i>FANCA</i> -16q24.3, <i>FANCB</i> -Xp22.31, <i>FANCC</i> -9q22.3, <i>FANCD1</i> [ <i>BRCA2</i> ]-13q12.3, <i>FANCD</i> -3p25.3, <i>FANCE</i> -6p22-p21, <i>FANCF</i> -11p15, <i>FANCG</i> -9q13, <i>FANCI</i> -15q25q26, <i>FANCI</i> [ <i>BRIP1</i> ]-17q22, <i>FANCL</i> -2q16.1, <i>FANCM</i> -14q21.3, <i>FANCN</i> [ <i>PALB2</i> ]-16p12, <i>FANCO</i> [ <i>RAD51C</i> ]-17q22, and <i>FANCP</i> [ <i>SLX4</i> ]-16p13.3)
De Sanctis–Cacchione (278800)	Xeroderma pigmentosum, hypogonadism, microcephaly	Autosomal recessive	<i>ERCC6</i> (excision repair cross-complementing) gene at 10q11
Johanson–Blizzard (243800)	Hypoplastic alae nasi, microcephaly, midline scalp defects, sensorineural deafness, exocrine pancreatic insufficiency, nasolacrimal system malformations, absent permanent teeth, hypothyroidism (112)	Autosomal recessive	<i>UBR1</i> (ubiquitin protein ligase E3 component N-recognin 1) gene at 15q15-q21.1
Donohue leprechaunism (246200)	Severe IUGR adipose deficiency, thick lips, islet cell hyperplasia results in hyperinsulinemia	Autosomal recessive	<i>INSR</i> (insulin receptor) gene at 19p13.2
Seckel syndrome (210600, 606744, 608664, 61376)	IUGR with microcephaly, prominent nose, micrognathia	Autosomal recessive, genetically heterogeneous	<i>SCKL1-ATR</i> (Ataxia-telangiectasia and RAD3-related) at 3q22.1q24 <i>SCKL2</i> —18p11.31–q11.2 (113) <i>SCKL3</i> —14q21–q22 (114) <i>SCKL4</i> — <i>CENPJ</i> -13q12.2 (115)
Hallermann–Streiff (234100)	Microphthalmia, small pinched nose, hypotrichosis, dental anomalies, cutaneous atrophy	Sporadic	
Smith–Lemli–Opitz (270400)	Deficiency of enzyme 7-dehydrocholesterol reductase. Prenatal-onset growth deficiency with postnatal persistence secondary to abnormal cholesterol metabolism. Microcephaly, ptosis, cleft palate, syndactyly of 2nd and 3rd toes, postaxial polydactyly, hypospadias (116)	Autosomal recessive	<i>DHCR7</i> at 11q12-q13 (117) (diagnostic test is elevation of serum 7DHC)
Williams (130160)	Prominent lips, periorbital fullness, supraaortic stenosis (or other cardiovascular disease), mild MR, specific cognitive profile (overly friendly), endocrine abnormalities (118)	Sporadic, autosomal dominant	Genes at 7q11.2 <i>ELN</i> gene <i>LIMK1</i> <i>GTF2I</i> <i>MAGI2</i> (119) <i>HIP1</i> <i>YWHAQ</i>
Noonan (163950)	Webbed neck, pectus excavatum, pulmonary stenosis, hypertelorism, downward slanting palpebral fissures, motor delay	Autosomal dominant	<i>PTPN11</i> gene 12q24.1. Also <i>SOS1</i> , <i>KRAS</i> , <i>BRAF</i> , <i>SHOC</i>

**TABLE 38-1 Prenatal-Onset Growth Deficiency Disorders—Cont'd**

Disorder	Key Clinical Findings	Inheritance	Gene Testing
Aarskog (100050)	Ocular hypertelorism, optic nerve hypoplasia, retinal vessel tortuosity, deficient ocular elevation, hyperopia, and anisometropia (120) brachydactyly, shawl scrotum,	X-linked	<i>FGD1</i> gene at Xp11.2 (121)
Robinow (180700)	Broad forehead with flat facial profile, short forearms, hypoplastic genitalia	Autosomal dominant Autosomal recessive	<i>ROR2</i> on 9q22 (122)
Opitz (300000)	Ocular hypertelorism, hypospadias, swallowing difficulties secondary to abnormalities of the trachea/esophagus and larynx; also associated with cardiac anomalies, imperforate anus, and developmental delay; anteverted nares and posterior pharyngeal cleft were seen only in the X-linked form. (122)	Autosomal dominant & X-linked	<i>MID1</i> on Xp22
Coffin–Siris (135900)	Hypoplastic 5th digits and nails, coarse facies, hirsutism with sparse scalp hair, psychomotor delay/MR (123)	Autosomal dominant	<i>ARID1B</i> at 6q25 and other <i>SWI/SNF</i> subunit genes (123)

also known as fetal growth restriction) (3,5,11). This is a very heterogeneous group of disorders with multiple causes ranging from placental insufficiency to teratogenic disorders to specific genetic and chromosomal syndromes. When other causes of IUGR have been ruled out, and placental pathology supports the diagnosis, uteroplacental insufficiency is used to identify fetuses whose poor growth is due to an inadequate placental supply of nutrition. Declining body growth in response to inadequate intra-uterine supply with relative preservation of brain growth is viewed as an adaptive response to protect fetal brain development. There is no agreement whether a diagnosis of SGA should be based on racial, ethnic, or gender norms, but most SGA infants are identified on the basis of their birth weight for gestational age. Infants delivered preterm (as a group) are much smaller than fetuses that remained in utero and delivered closer to term, and these data suggest an overlap between preterm birth and IUGR. When preterm IUGR infants and infants of multiple gestations are born after 33–34 weeks gestation, they may have fewer complications of prematurity than expected for their gestational age, while infants born with IUGR before 34 weeks gestation have greater mortality and morbidity than preterm appropriate-for-gestational-age infants of the same gestational age. These factors must be taken into account while comparing growth parameters at birth with subsequent growth and development.

In many cases, a specific diagnosis of a recognizable syndrome can be made on the basis of associated characteristic clinical findings (e.g. Brachmann–de Lange syndrome (Figure 38-3A), Rubinstein–Taybi syndrome (Figure 38-3C), Russell–Silver syndrome (Figure 38-2), Johanson–Blizzard syndrome, Hallermann–Streiff syndrome, Williams syndrome (Figure 38-3B), Noonan syndrome (Figure 38-3D), or Aarskog syndrome (Figure 38-3E).) In some cases, limb malformations may represent distinctive features of the syndrome (e.g. Brachmann–de Lange syndrome

or Rubinstein–Taybi syndrome) (Table 38-1). Thus, the clinical evaluation and analysis of the dysmorphic features present in each case often permits reaching a conclusive diagnosis.

In certain syndromes, diagnosis can be supported by specific laboratory studies, such as an increased rate of sister chromatid exchanges in Bloom syndrome (now confirmed by mutation analysis of the DNA helicase gene *BLM*) (12); analysis of chromosome breakage in the Fanconi pancytopenia syndrome, which can be caused by mutations in at least 15 different genes (13); assessment of DNA repair genes in Cockayne syndrome, cerebro-oculofacial-skeletal syndrome (Figure 38-3F), and xeroderma pigmentosum (14,15); use of array comparative genomic hybridization (CGH) in Williams syndrome (Figure 38-3B) or velocardiofacial syndrome; and insulin receptor mutation analysis in leprechaunism (caused by mutations in the insulin receptor gene *INSR* at 19p13.2). As more genes for various syndromes become known, mutation analysis via clinical molecular testing will become more available and useful, but such testing seldom demonstrates mutations in 100% of cases, so clinical diagnosis is still the basis for diagnosing many recognizable syndromes. For families with a known mutation demonstrated in a research laboratory, this mutation can be confirmed in a clinical molecular laboratory and used for clinical purposes. Array CGH is rapidly replacing chromosome analysis and fluorescence in situ hybridization (FISH) analysis and can also be used to uncover the genomic basis for previously unknown causes of syndromic short stature, as well as to detect the deletion of a gene when mutation analysis of the causative gene demonstrates a normal sequence.

Some proportionate growth deficiency syndromes are inherited as autosomal recessive disorders, such as Bloom, Donohue, and microcephalic osteodysplastic primordial dwarfism type II (MOPDII), whereas others usually occur

(A)

(B)

**FIGURE 38-2** (A) This 3-year-old child with Russell–Silver syndrome had prenatal-onset growth deficiency that persisted after birth, triangular facial shape, fifth finger clinodactyly, mild skeletal asymmetry and reduced adipose tissue that placed this child at risk for fasting hypoglycemia. (B) This 4.5-year-old child with Russell–Silver phenotype did not respond to growth hormone and developed subtle skeletal signs of 3M syndrome.

sporadically, such as Hallermann–Streiff, Rubinstein–Taybi, Russell–Silver, Brachmann–de Lange, and Williams syndromes. Some disorders, such as Brachmann–de Lange syndrome and Noonan syndrome, are genetically heterogeneous and may be due to a new mutation. Others may result from either a gene mutation or a submicroscopic chromosomal deletion, as seen in Rubinstein–Taybi syndrome. In such cases, both mutation analysis and FISH or CGH analysis may be necessary, because if there is a whole-gene deletion and mutation analysis is undertaken, only the remaining normal allele will be sequenced and will be found to have a normal coding sequence.

**38.2.1.2 Chromosomal Disorders.** With the exception of sex chromosome aneuploidy, trisomy 21, and trisomy 8 mosaicism, most chromosomal disorders result in some degree of IUGR (see Chapters 43–45). In those syndromes compatible with survival beyond infancy, such as Turner syndrome and a variety of autosomal

partial deletion or duplication syndromes, there is continued diminished growth throughout childhood and a blunted pubertal growth spurt as well. As the number of recognized chromosomal disorders increases because of new technologies, such as array CGH, it remains important to make an accurate clinical diagnosis to select the appropriate laboratory techniques. A patient with IUGR, developmental delay, and dysmorphic features who does not manifest a recognizable syndrome may have an underlying genomic disorder, which could be detected by array CGH. For example, deletion of 1q24q25 can result in primordial short stature with severe microcephaly due to deletion of the *CENPL* gene, a centrosomal gene (16), and deletion of 12q14 can result in short stature possibly secondary to the deletion of *HMGA2* (17).

In patients with a symptom complex suggestive of a specific chromosomal deletion syndrome (e.g. 4p- syndrome Figure 38-4 or 18q- syndrome Figure 38-5), it may be useful to begin the diagnostic evaluation with array CGH, particularly if previous chromosomal studies were normal. Some chromosomal syndromes may only be detectable in skin fibroblast samples (e.g. diploid–triploid mixoploidy or tetrasomy 12p). It is also important to remember that some girls with Turner syndrome, especially those with mosaicism, express few phenotypic features prepubertally, except for short stature. Thus chromosomal studies should be done on girls who appear to be short for their family background, with relatively normal body proportions, and for whom another diagnosis has not been made.

Several chromosomal deletion syndromes have also been found to be associated with growth hormone (GH) insufficiency, indicating the locations of genes or chromosomal regions that result in short stature. Since the *GH1* gene is on 17q22–q24, the growth hormone receptor *GHR* gene on 5p13–12, the *IGF1* gene on 12q22q24.1, and the *IGF1R* receptor gene on 15q25q26, it is not surprising that mutations or deletions of any one of these genes will result in growth deficiency, often on an autosomal recessive basis (18). Likewise, Donohue syndrome (leprechaunism) is due to mutations in the insulin receptor gene on 19p13.2, resulting in insulin resistance and IUGR, since insulin is a major fetal growth factor (Chapter 86). For some of the more common short stature and chromosome disorders, syndrome-specific growth curves are available through the Internet to aid in following these patients, and these curves are quite useful for detecting when secondary hormonal problems might be present. Growth deficiency in Turner syndrome has been attributed to haplo-insufficiency of the *SHOX* gene at Xpter-p22.32 (19), and altered imprinting on chromosome 7 or 11p15 has been identified in around half of patients with Russell–Silver syndrome (20). Autosomal recessive disorders such as 3M syndrome and Bloom syndrome also need to be considered in patients with the Russell–Silver phenotype.

(A)

(B)

**FIGURE 38-3** (A) This child with classic Brachmann-de Lange syndrome has not had any testing to determine the cause for her disorder. (B) This child (left) with typical facial features for Williams syndrome and supravalvular aortic stenosis with peripheral pulmonic stenosis has an atypical 1.26–1.31 Mb deletion that includes *GTF2IRD1* but not *GTF2I*. She has typical visual-spatial construction defects without the usual increased eye contact and indiscriminant approach to strangers seen in children with the typical 1.55 MB deletion that includes *GTF2I*, illustrating the usefulness of chromosomal microarrays in understanding the clinical features of Williams syndrome. On the right are shown children with the typical deletion at different ages.

(C)

(D)

(E)

**FIGURE 38-3—cont'd** (C) This infant (top left) with Rubinstein-Taybi syndrome shows the characteristic facial features, with broad and often angulated thumbs and great toes, short stature, and moderate to severe mental retardation. The characteristic craniofacial features include downslanting palpebral fissures with nasal columella extending below the nares. The individual on the bottom left is shown at age 4 years and age 30 years with similar features due to a 169.92 kb deletion on 16p13.3 which included *CREBBP*. (D) These two children with Noonan syndrome show similar facial features with proportionate short stature, hypertrophic cardiomyopathy (left) and ASD with pulmonic stenosis (right). Both had feeding problems, with mildly delayed development later. (E) This child with Aarskog syndrome has proportionate short stature, ocular hypertelorism, anteverted nostrils, broad upper lip, with shawl scrotum, hyperextensible fingers, wide flat feet, ovoid periumbilical depression and ADHD.

(F)

**FIGURE 38-3—cont'd** (F) This 12-year-old boy with Cockayne syndrome (top) is the size of a two-year-old with typical features of Cockayne syndrome. These dizygotic twins with cerebro-oculofacial-skeletal (COFS) syndrome were from the Manitoba aboriginal family that was first reported with this syndrome. They were found to have a mutation in CSB, confirming that COFS syndrome and Cockayne syndrome are allelic (From Meira, L. B.; Graham, J. M., Jr, et al. *Am. J. Hum. Genet.* **2000**, 66, 1221–1228.)

**FIGURE 38-4** Two patients with 4p-syndrome (Wolf-Hirschhorn syndrome). Note ocular hypertelorism, with cleft lip in a patient on the left. Also present were hypospadias and preauricular pits with severe cognitive disability and intrauterine growth deficiency that persisted after birth.

**FIGURE 38-5** This patient with 18q-syndrome has typical mid-face deficiency, conductive hearing loss, deep-set eyes, prominent antitragus and long palms with proximally placed thumbs and long tapered fingers.

**38.2.1.3 Teratogens.** A variety of teratogenic exposures are associated with IUGR (Table 38-1) (see Chapter 36). Although maternal smoking may result in otherwise normal SGA babies, most other teratogens result

in well-characterized teratogenic syndromes. It must be stressed, however, that the clinical variability in these teratogenic syndromes is great, and it is the exceptional case that has all the features of a teratogenic syndrome. Therefore, a careful history of maternal drug and teratogen ingestion must be taken for all children who demonstrate IUGR. The most frequent teratogenic cause of growth deficiency is fetal alcohol syndrome (Figure 38-6). Maternal disease that can result in the accumulation of

**FIGURE 38-6** This 8-year-old girl with fetal alcohol syndrome has mild cognitive disability, ADHD, proportionate short stature, microcephaly, short palpebral fissures, short nose, thin smooth upper lip, and camptodactyly with mild fingertip and nail hypoplasia.

toxic substances that cross the placenta also can result in teratogenic effects on the fetus. This is clearly evident in the maternal phenylketonuria syndrome (5). Intra-uterine infections with rubella, syphilis, toxoplasmosis, and cytomegalic inclusion disease can produce prenatal growth retardation that results in postnatal proportionate short stature. Affected neonates may show systemic manifestations, including microcephaly, chorioretinitis, hepatosplenomegaly, petechiae, and seizures. The diagnosis should be suspected at birth, so that appropriate studies can be done to document the diagnosis and initiate therapy.

### 38.2.2 Proportionate Short Stature of Postnatal-Onset

Persons with postnatal-onset proportionate short stature usually have some kind of postnatal environmental insult, such as a chronic disease or an endocrine disorder, all of which may be associated with decreased insulin-like growth factor (IGF) or peripheral unresponsiveness to its action (Chapter 83). There may be direct suppression of hepatic IGF synthesis, deficient GH secretion with

secondarily reduced IGF production, inability to respond to GH stimulation of IGF, circulating IGF inhibitors, or peripheral unresponsiveness to the actions of IGF. These children usually have a bone age commensurate with, or even more severely retarded than, their height age, depending on the state of their gonadal and thyroid systems.

An accurate diagnosis is especially important for persons with this group of disorders because many of them will respond to specific therapeutic measures.

**38.2.2.1 Psychosocial Dwarfism.** In certain children, emotional disturbances may result in pronounced growth retardation (21). Although these children usually come from homes where marital discord, separation, alcoholism, and social upheaval are found, they can also be seen in well-to-do and seemingly well-adjusted families. There is usually a poor plasma GH response to GH stimulation tests, and levels of circulating IGF are low. Bone age maturation is usually greatly delayed. When removed from their adverse environment, these children usually show a striking catch-up in their bone age, and GH and IGF levels return to normal. Psychosocial dwarfism is thought to represent functional hypopituitarism in which psychological factors have produced a pituitary insufficiency through hypothalamic suppression. This condition appears to be relatively common, but it usually occurs in only one member of a family.

**38.2.2.2 Malnutrition.** Chronic malnutrition retards growth and is associated with reduced synthesis of IGF (22). The absence of an adequate substrate for growth may contribute to growth failure in malnutrition as well. Malnutrition resulting from malabsorption may also result in growth retardation (23). Asymptomatic celiac disease can result in proportionate growth retardation (24). Small-bowel biopsies are sometimes helpful in the workup of such children in whom other causes of growth retardation have been excluded.

**38.2.2.3 Chronic Disease.** Many chronic childhood diseases are associated with growth failure. Chronic liver disease, renal disease, celiac disease, regional enteritis, infectious disease, diabetes mellitus, hemoglobinopathies, asthma, congenital heart disease, and many others fit into this category. Often, reduced growth may be the dominant clinical feature. Low IGF levels are usually found, and, in addition, many patients are in a state of negative nitrogen balance. After cure or control of the basic disease, there is usually significant catch-up growth, and some children may ultimately reach a near-normal final adult stature, depending on the duration and severity of the disease, the age at the onset of the disorder, and its therapy. For example, children with celiac disease and persistent short stature may reach normal stature when treated with GH (24).

**38.2.2.4 Drug Administration.** In addition to various intrinsic causes of reduced human GH secretion, certain medications used in treating hyperactivity, such as methylphenidate hydrochloride or dextroamphetamine,

may alter the normal regulation of GH (25,26). Children often show reduced growth rates during the first few years after treatment commences, but tolerance to the growth suppression may develop later. Similarly, glucocorticoids used in treating certain diseases, such as asthma, nephrotic syndrome, juvenile rheumatoid arthritis, and leukemia, may significantly retard growth. The growth-suppressing effects of steroids may be seen with relatively small doses that are often thought to be harmless, such as prolonged use of topical ointments, nasal spray, or eye drops containing these compounds. The long-term effects of these and other drugs on final adult height have not been well established.

**38.2.2.5 Endocrine Disorders.** Many disturbances in the endocrine system can impair growth (18). Thyroid hormone deficiency can result in either proportionate or disproportionate short stature, depending on the degree of secondary epiphyseal dysplasia. Cushing disease can lead to proportionate short stature similar to that seen with the exogenous administration of steroids. Excess androgen secretion, as in the adrenogenital syndrome, can lead to accelerated growth with advanced bone age in early childhood but significant adult short stature resulting from premature closure of epiphyses (see Chapters 84 and 87). The prototype of endocrine short stature is GH deficiency. GH-related causes of short stature can result from many interruptions in the hypothalamic–pituitary–peripheral tissue axis. The various types of pituitary dwarfism can be classified on the basis of the level of the defect, whether genetic or acquired. If genetic, is it associated with an obvious developmental or degenerative disease of the hypothalamus? If pituitary, is the deficiency monotropic (isolated GH deficiency) or multitropic? Is it due to a defect in GH action; is IGF generation normal or defective (18)? The most common causes of acquired pituitary insufficiency are birth trauma, cranial irradiation for neoplasia, craniopharyngioma with the expanding tumor mass compromising pituitary function, and hemosiderosis following chronic transfusion therapy. In addition, trauma, surgical damage, infection, and sarcoidosis can also lead to pituitary insufficiency.

**38.2.2.6 Developmental Anomalies and Genetic Syndromes Associated with Hypopituitarism.** A number of developmental anomalies or genetic syndromes affecting the hypothalamus and pituitary may result in GH deficiency with or without other tropic hormone deficiencies (see Chapter 83). Many of these syndromes are associated with facial or optic anomalies. In certain disorders, such as congenital absence of the pituitary, empty sella syndrome, transsphenoidal encephalocele, and two rare syndromes associated with an unusual or large sella turcica, lateral skull radiographs may be sufficient to suspect the intracranial anomaly. In other disorders, however, such as holoprosencephaly and septo-optic dysplasia, magnetic resonance imaging of the brain and hypothalamus may be necessary to detect the malformations. Therefore, any

GH-deficient child with malformations of the face or eyes should have imaging of the brain and sella turcica to rule out a malformation affecting the hypothalamus or pituitary gland.

A number of genetic syndromes that are not associated with known developmental malformations of the hypothalamus or pituitary have pituitary insufficiency as a common component. Children with Pallister–Hall syndrome (hypothalamic hamartoma or hamartoblastoma, polydactyly, anal or renal anomalies, and facial changes) may present with hypopituitarism, and this disorder is caused by mutations of *GLI3* (27). In other disorders, such as histiocytosis X and hemochromatosis, the hormonal deficiencies are due to a degenerative disease of the hypothalamus and pituitary. In other syndromes, however, the pathogenesis of the pituitary insufficiency is unknown. Both sickle cell anemia and thalassemia are associated with delayed growth and sexual development that result in adult short stature. In thalassemia, this is apparently due to post-transfusion therapy, resulting in hemosiderosis that affects the pituitary. In persons with sickle-cell anemia, the exact cause of the short stature is unknown.

**38.2.2.7 GH Deficiency Unassociated with Developmental Anomalies or Multisystem Genetic Syndromes.** The most common form of GH deficiency is the “idiopathic type” (i.e. one in which no organic lesions exist). This heterogeneous group of disorders can be classified on the basis of whether only GH is deficient or there are multitropic hormone deficiencies, and if it is genetic or acquired. In addition, these disorders must be distinguished from the various forms of IGF or GH resistance. Prenatal problems, such as breech or forceps deliveries, early vaginal bleeding, or prolonged or unusually short labors, frequently occur in persons with acquired hypopituitarism, as do signs of intrapartum fetal stress or anoxia. It has been suggested that these perinatal insults lead to the hypopituitarism in the nongenetic forms of this disease. The many genetic forms of GH deficiency or resistance are discussed in Chapter 83.

### 38.2.3 Disproportionate Short Stature

If a disproportionate body habitus is found on physical examination, the patient is likely to have a form of skeletal dysplasia (Chapter 158). This is a heterogeneous group of heritable disorders affecting skeletal connective tissues in which the predominant clinical feature is dwarfism.

The osteochondrodysplasias have been divided into 37 groups of disorders and 3 groups of dysostoses based on clinical and radiographic features (2). Furthermore, each of these disorders is associated with a variety of skeletal and nonskeletal complications, so that an accurate diagnosis will help the clinician to develop a realistic treatment plan. These osteochondrodysplasias and dysostoses have also been classified

using molecular, pathogenetic, and developmental approaches based on the structure and function of the causative genes and proteins; these classification systems are discussed in detail by Warman et al. (2). As illustrated in Figure 38-1, the diagnostic workup for short stature should be approached rationally, before determining the mode of therapy. Disproportionate short stature may require a therapeutic approach entirely different from what is used for proportionate short stature.

Likewise, prenatal-onset disorders must be separated from postnatal-onset disorders, and each category of growth deficiency will manifest different responses to specific treatments. In general, prenatal-onset growth deficiency that persists after birth is generally assumed to be due to a genetic, syndromal, cytogenetic, or teratogenic disorder that results in generalized hypoplasia or disproportionate skeletal hypoplasia. Growth deficiency that is secondary to chronic disease, endocrine insufficiency, nutritional insufficiency, or psychosocial deprivation responds best to treatment of the primary disease state. Recurrence risk counseling must also be individualized based on the underlying diagnosis.

The use of more advanced molecular genetic and cytogenetic techniques has augmented the clinical diagnosis of known syndromes and has helped define clinically recognizable syndromes based on gene mutation analysis and copy number variants that were previously undetectable using standard cytogenetic techniques (16,17).

### 38.3 PATHOLOGIC OVERGROWTH

The array of pathologic conditions that can result in overgrowth is more restricted than the numerous conditions that have a negative impact on growth. There are a number of growth factors that function at various times during development and impact the growth of specific tissues in either a generalized or localized way. Similarly, other factors function to suppress growth. Thus, overgrowth disorders result in either localized or generalized effects on growth.

As with short stature, the pathologic determination of overgrowth should be made in relation to family and ethnic background. Once a careful assessment is made and pathologic overgrowth is apparent, every effort should be made to reach an accurate diagnosis in order to provide adequate medical management and genetic counseling. Most prenatal overgrowth disorders persist after birth, and, in some cases, mental deficiency, risk for tumor development, or both, are important associated features. The risk for tumor development usually involves embryonal neoplasms, perhaps related to overexpression of growth factors or lack of suppressing factors. A comprehensive review of overgrowth disorders has been presented in *Gorlin's Syndromes of the Head and Neck* (4).

#### 38.3.1 Generalized Overgrowth Disorders

The optimum birth weight for the lowest perinatal mortality and morbidity is 3500–4000g, with 5% of newborns exceeding 4000g and 0.5–1% exceeding 4500g (28). Factors related to large fetal weight include genetic predispositions; excessive maternal weight gain, obesity, and diabetes; postmaturity; and multiparity (29). Although many macrosomic infants demonstrate proportionate overgrowth, infants of diabetic mothers are often disproportionately overgrown, with increased weight-to-length ratios. Infants born to diabetic and/or obese mothers also have an increased risk for certain malformations (30,31). Some infants with anasarca are macrosomic primarily due to increased extracellular fluid volumes. True somatic overgrowth is often accompanied by increased placental size, as is commonly seen in Beckwith–Wiedemann syndrome (BWS) (32,33).

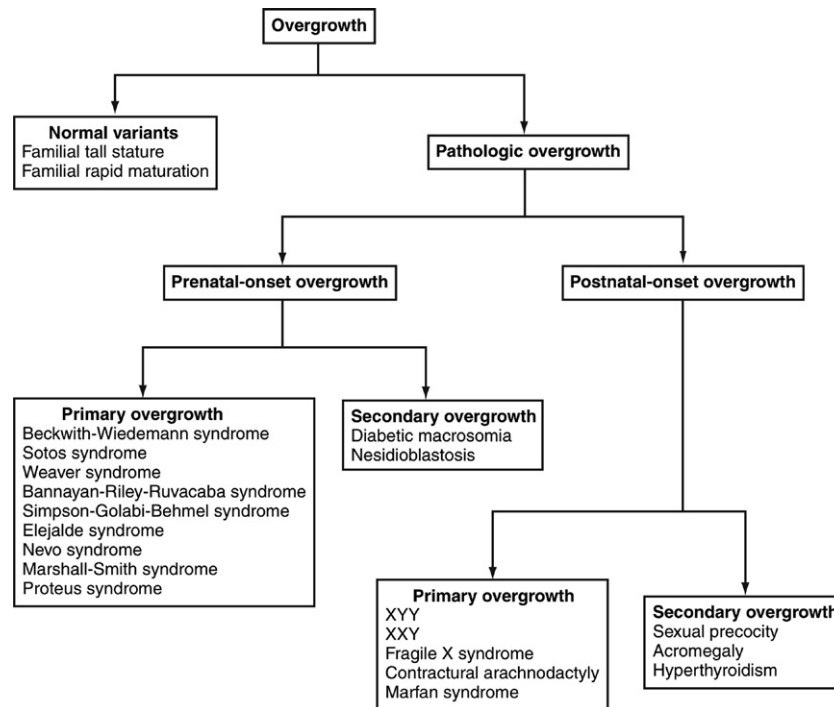

At the cellular level, the onset of most prenatal overgrowth results from (1) excessive cellular proliferation (hyperplasia), (2) excessive cellular size (hypertrophy), (3) an increase in the interstitium (e.g. anasarca), or (4) a combination of these factors. Overgrowth conditions can be subdivided between normal variants, such as familial tall stature or familial rapid maturation, prenatal-onset growth excess, or postnatal-onset growth excess (Figure 38-7). However, primary growth excess results from intrinsic cellular hyperplasia, while secondary growth excess is due to humorally mediated factors outside the skeletal system.

Among pathologic overgrowth disorders, most prenatal-onset growth excess is of the primary type, as is seen with BWS or Sotos syndrome. Secondary growth excess of prenatal-onset is usually not syndromic. The best examples include diabetic macrosomia and congenital nesidioblastosis (34).

In this disorder, a diffuse abnormality of the pancreas results in extensive and often disorganized formation of new islets of Langerhans, overproduction of insulin, and consequent severe neonatal hypoglycemia requiring pancreatectomy. Persistent hyperinsulinemic hypoglycemia of infancy is caused by mutations in the beta-cell high-affinity sulfonylurea receptor gene (*SUR1*) (35) or in the inwardly rectifying potassium channel gene (*KCNJ11*), and both these genes are located on 11p15, where the phenotype of persistent hyperinsulinemic hypoglycemia of infancy has been mapped (36). Autosomal dominant familial hyperinsulinism has been shown to be due in some instances to an activating mutation in the glucokinase gene (*GCK*) or, associated with hyperammonemia, in the *GLUT1* gene (37).

Postnatal-onset growth excess is usually secondary, involving overproduction of estrogens or androgens (precocious puberty), overproduction of GH (acromegaly), or overproduction of thyroid hormone. A few primary excess growth disorders manifest the majority of their overgrowth in the postnatal period (e.g. XYY syndrome,

**FIGURE 38-7** Classification of overgrowth disorders.

XXY syndrome, fragile X syndrome, and Marfan syndrome). The management of these syndromes is discussed in detailed in Chapters 44, 107, and 153.

**38.3.1.1 Prenatal Overgrowth Syndromes.** It is important to recognize the major diagnostic features for prenatal-onset overgrowth syndromes. Because of their importance and frequency, a few of these disorders are discussed in more detail in the following sections.

**38.3.1.2 Cerebral Gigantism (Sotos Syndrome).** Although the exact prevalence is not known, Sotos syndrome is estimated to be between 1:10,000 and 1:50,000; the diagnosis is largely based on clinical examination, and the features have been well described (38). Cerebral gigantism is associated with prenatal-onset overgrowth and affects length more than weight. Rapid linear growth, more pronounced in the first year of life, is accompanied by variable advanced osseous maturation and large hands and feet (39). The head is usually large and dolichocephalic with frontoparietal balding. The facial features are distinctive: the round face with a disproportionately prominent forehead seen in infancy elongates with age to a slim face with a pointed chin seen in adolescence (40). Other distinctive facial features include flushed cheeks and premature eruption of teeth (41) (Figure 38-8).

Complications commonly seen in the neonatal period include jaundice secondary to hyperbilirubinemia or hypoglycemia, often associated with hypotonia and difficulties with feedings secondary to trouble sucking or swallowing and gastroesophageal reflux (40). In addition, there are a number of neurological features to Sotos syndrome including developmental delay affecting

the development of both motor and speech functions, with associated clumsiness, and electroencephalographic abnormalities. There is a wide spectrum of psychosocial and behavioral problems with some degree of learning difficulties and risk of developing attention deficit disorder, hyperactivity disorder, and temper tantrums (42–44). On cranial imaging, there is delayed or underdevelopment of the brain, particularly of midline structures (45). Defects most commonly seen include dilation of cerebral ventricles (46) and hypoplastic or absent corpus callosum (47). Other defects seen in Sotos syndrome may include cardiac defects, usually atrial septal defect or patent ductus arteriosus (PDA) (46,48), and genitourinary anomalies (41). Although difficult to predict, final height tends to normalize after puberty with the most prominent feature seen in adults being macrocephaly (38).

Most cases are sporadic occurrences in otherwise normal families, with associated increased paternal age and de novo point mutations or whole-gene deletion of *NSD1* on 5q35. Roughly 93% of cases of Sotos syndrome result from a mutation of *NSD1*. In Japan, the frequency of mutations is marginally lower (83% *NSD1* mutations) and deletions are more frequent (10%) (49). Autosomal dominant inheritance has been demonstrated in some cases, with the affected parent showing mild mental retardation, long facies, and large hands and feet, but without tall stature (38). Based on a review of the literature, the tumor frequency of patients with Sotos syndrome is 3.9% (4).

**38.3.1.3 Weaver Syndrome.** In Weaver syndrome, overgrowth is usually evident at birth, with most affected

(A)

(B)

**FIGURE 38-8** (A) This 3-year-old girl with Sotos syndrome demonstrates typical facial features macrocephaly, dolichocephaly, frontoparietal balding, down-slanted palpebral fissures, flushed cheeks, prominently pointed chin, with premature eruption of teeth and accelerated osseous maturation. (B) Both these boys have Sotos syndrome with similar facial features, but the boy on the left has a NSD1 mutation with normal cognitive skills and the boy on the right is deleted for NSD1 with cognitive disability, a tethered cord and sacral malformations.

individuals at or above the 97th percentile for length and weight by age 1 year (4). Overgrowth continues throughout life, with adult height and weight above the 97th percentile, and markedly accelerated osseous maturation during childhood. Most affected individuals are mentally deficient. Their distinctive features include hypertonia, hoarse low-pitched cry, macrocephaly, round face, ocular hypertelorism, downslanting palpebral fissures, long philtrum, large ears, micrognathia, camptodactyly, clinodactyly, broad thumbs, prominent fingertip pads, and limited elbow and knee extension (Figure 38-9). Younger children with Weaver syndrome have been known to have difficult airways to intubate secondary to the relative micrognathia, anterior and cephalad positioning of the larynx, and a relatively short neck; this difficulty seems to decrease with the growth of the mandible over

**FIGURE 38-9** Both these unrelated boys have Weaver syndrome at ages 18 months and 11 months (From Weaver, D. D.; Graham, C. B.; Thomas, I. T.; Smith, D. W. A New Overgrowth Syndrome with Accelerated Skeletal Maturation, Unusual Facies, and Camptodactyly. *J. Pediatr.* **1974**, 84, 547–552.)

**FIGURE 38-10** This infant with Beckwith-Wiedemann syndrome was born macrosomic with macroglossia, omphalocele, glabella, nevus flammeus, infraorbital creases, and posterior auricular ear pits. These are typical features in this common overgrowth disorder.

time (50). Frequency of solid tumors and hematologic malignancies among reported literature cases was found to be 10.9% (51), but this may be an overestimate based on a failure to report cases of Weaver syndrome uncomplicated by malignancy. Weaver syndrome is caused by *de novo* mutations in *EZH2* (including one of the original two patients on Figure 38-9 (125).

**38.3.1.4 Beckwith-Wiedemann Syndrome.** BWS is the most common congenital overgrowth syndrome, with a frequency of 1 case per 13,700 births (33). It is associated with abdominal wall defects, macroglossia, prenatal-onset overgrowth, neonatal hypoglycemia, and visceromegaly. Other distinctive features include earlobe creases and pits, facial nevus flammeus, and infraorbital creases (Figure 38-10). Patients with BWS may have elevated serum alpha fetoprotein (AFP) levels postnatally, which tend to decrease over the first year of life at a slower rate than in normal children, (53) but this

elevated AFP is not yet attributed to an increased risk for hepatoma or other known causes of elevated AFP in the general adult population. Large size at birth is associated with placental overgrowth, long umbilical cord, and polyhydramnios, which may result in premature delivery, contributing to an increased perinatal mortality (54). The large size for age continues through early childhood and is associated with accelerated osseous maturation, but overgrowth is usually no longer evident by adulthood. Prompt recognition of this disorder is important because of the dangers associated with hypoglycemia and prematurity in overgrown neonates and associated risk for embryonal neoplasms affecting abdominal organs (primarily nephroblastoma, adrenocortical carcinoma, and hepatoblastoma). Intelligence is usually normal in the absence of complications related to prematurity and/or neonatal hypoglycemia.

BWS is caused by genetic alterations in chromosomal region 11p15, an area that is subject to imprinting (it is also known as the BWS critical region) and functionally separated into two regions: imprinting cluster 1 (IC1), regulating the expression of *IGF2* and *H19*, and IC2, regulating the expression of *KCNQ1*, *CDKN1C*, and *KCNQ10T1*. These regions are differentially methylated (IC1 is normally methylated on the paternal 11p15, and IC2 is normally methylated on the maternal 11p15). For example, *IGF2* is a paternally active growth-enhancing gene with imprinting of the maternal allele, while *H19* appears to be a maternally active growth suppressor gene with imprinting of the paternal allele. About 80% of cases of BWS can arise through one of the following molecular presentations (as detected by genetic testing):

- (1) Methylation at IC2 on maternal chromosome is abnormal/lost (~50 percent cases BWS) (54).
- (2) There is gain of methylation at IC1 on the maternal chromosome (~5 percent of BWS cases) (54).
- (3) There is mutation of the maternal *CDKN1C* allele (in 40% of patients with a positive family history of BWS) (55). Cleft palate can be associated with BWS when there are mutations in the gene (54).
- (4) Cases have paternal uniparental disomy of 11p15 (about 20% of cases) (56) (Figure 38-11) or maternal translocations or inversions with breakpoints in 11p15.

Familial cases (15% of all people diagnosed with BWS) are inherited in an autosomal dominant fashion with incomplete penetrance, and most are born to female carriers. Sporadic cases can arise through de novo germ line or somatic mutations. Among cases with normal chromosomes, paternal uniparental disomy is present in 10–20% of cases, and somatic mosaicism for partial paternal isodisomy occurs in some cases of hemihyperplasia (54). About half of the sporadic cases show biallelic expression of *IGF2*. Hemihyperplasia (Figure 38-12) rarely occurs in familial cases, and hemihyperplasia and neoplasms seem to occur more frequently in sporadic

**FIGURE 38-11** This fetus has a paternally derived duplication of 11p15 with deletion of 18q- due to inheriting an unbalanced 11p;18q chromosomal translocation. She shows features of both disorders with large size and macroglossia plus clubfeet and abnormal hands.

cases, possibly because of an imbalance in the biallelic expression of *IGF2* and *H19*. Paternal trisomy or uniparental disomy for 11p15 could lead to an excess of expressed paternal alleles, while relaxation of the maternal imprint for 11p15 might give rise to biallelic expression of *IGF2* and/or suppression of *H19*. Overexpression of *IGF2* appears to be the most common pathogenetic mechanism for prenatal overgrowth.

Because of the risk of tumor development in BWS and in some common types of congenital hemi-hypertrophy, Shuman et al. (54) recommends the following screening protocol: (1) baseline abdominal computed tomography scan at age 6 months (or at the time of initial diagnosis);

**FIGURE 38-12** This boy was born with hemihyperplasia of the right side of his body, including his tongue. These features are usually sporadic and noninheritable. They are typical of the features seen in paternal uniparental disomy for 11p15, which is with the highest risk for hepatoblastoma and Wilms tumor.

(2) abdominal ultrasound every 3 months until age 7 years, then every 6 months until completion of skeletal growth; (3) abdominal palpation and urinalysis every 3 months until age 7 years, then every 6 months until skeletal maturity; and (4) annual analysis of serum AFP because of the risk of hepatic tumor development. Patients with hemihyperplasia may need more frequent determinations because of their increased risk for hepatoblastoma (54).

**38.3.1.5 Simpson–Golabi–Behmel Syndrome.** This distinctive X-linked syndrome, with partial expression in female carriers, was confused with BWS in earlier reports because of striking prenatal-onset overgrowth, which persists into adulthood. Features of this syndrome, which can aid in prenatal diagnosis, include an increased amniotic fluid AFP and increased nuchal translucency accompanied by body wall edema. By 30 weeks of gestation, macroglossia, polyhydramnios, nephromegaly, and hepatosplenomegaly, in addition to macrosomia, may also aid with prenatal diagnosis (57). Distinctive features include congenital macrocephaly, normal intelligence to severe mental deficiency (language delay most characteristic), ocular hypertelorism with short broad nose, cleft palate, wide mouth, central groove of the lower lip, supernumerary nipples, pectus excavatum, rib and vertebral abnormalities, hypotonia, postaxial polydactyly of the hands, nail hypoplasia (especially involving the index fingers) (58), partial cutaneous syndactyly, cryptorchidism, heart defects, and large cystic kidneys (59). Malformations of the central nervous system (CNS) include agenesis of the corpus callosum, Chiari malformations and hydrocephalus (60), and aplasia of the cerebellar vermis (59). Features in common with BWS include prenatal overgrowth, macroglossia, earlobe creases and pits, umbilical hernia, intestinal malrotation, and hypoglycemia from excessive

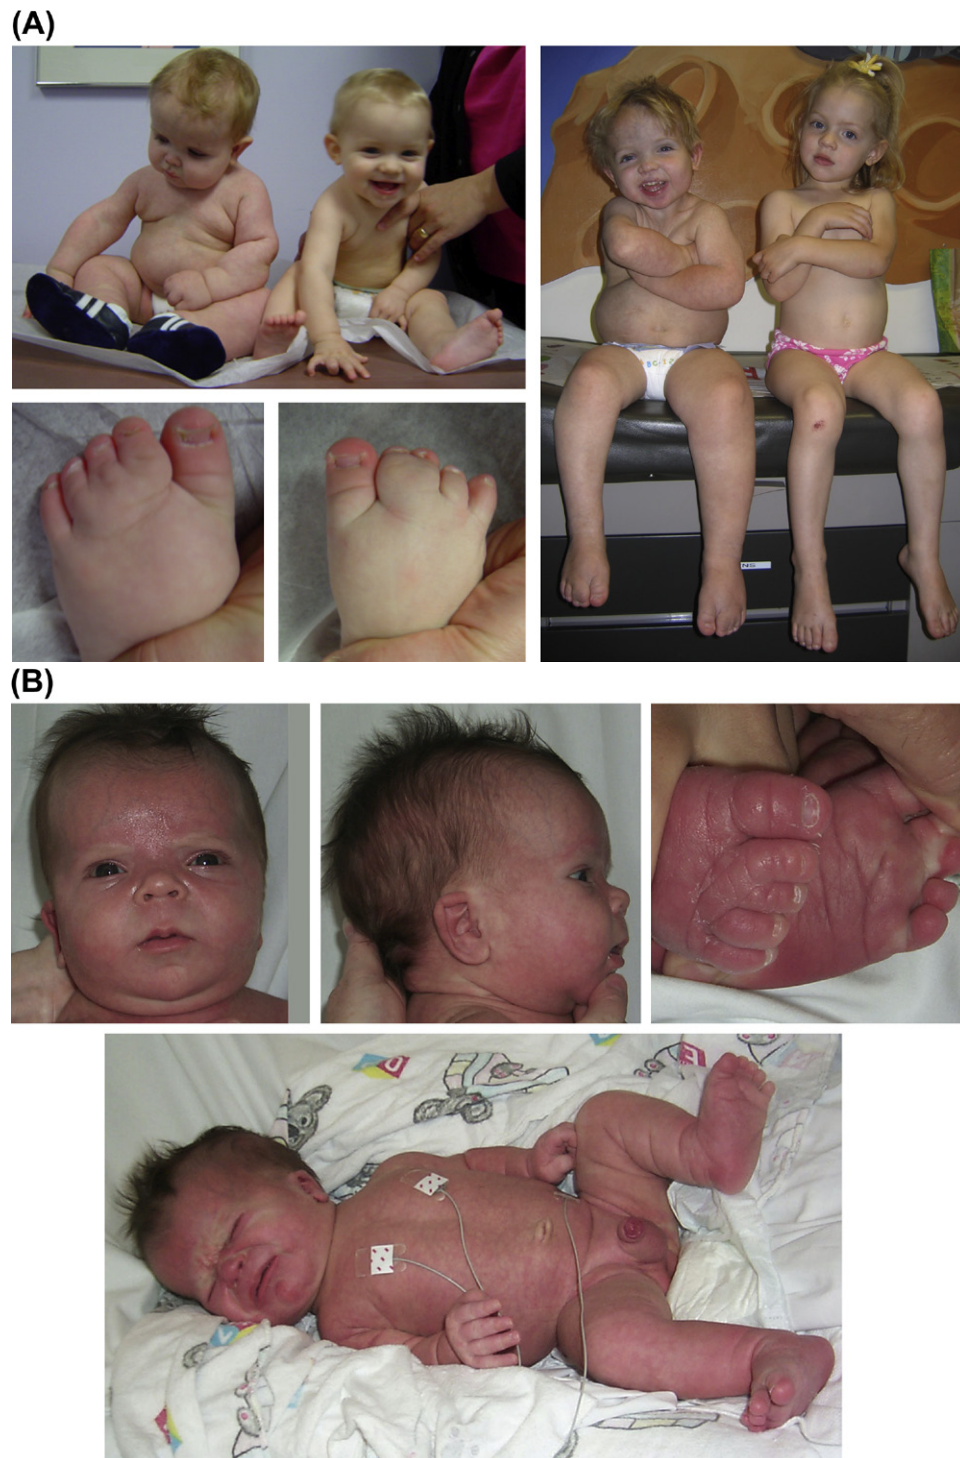

islets of Langerhans. Infant mortality is approximately 50%, occurring primarily from cardiorespiratory causes. This disorder results from mutations in the cell surface heparan sulfate proteoglycan glypican gene *GPL3*, which appears to play a role in controlling the growth of mesodermal tissues and binds to *IGF2*, whereby it helps to modulate its action (61). The reported frequency of tumors is 10% (59,62), including Wilms tumor, hepatoblastoma, adrenal neuroblastoma, gonadoblastoma, and hepatocellular carcinoma (63).

**38.3.1.6 PTEN Hamartoma Tumor Syndrome.** *PTEN* hamartoma tumor syndrome is an umbrella term used to cover the continuum of autosomal dominant overgrowth conditions including Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome associated with multiple hamartomas and detectable mutations of the *PTEN* gene (64,65). Cowden syndrome is a hamartomatous disorder with pathognomic features including cerebellar dysplastic gangliocytoma (adult Lhermitte–Duclos disease) and mucocutaneous lesions including facial trichilemmomas, acral keratoses, mucosal lesions, and papillomatous lesions. Other major features of this syndrome include macrocephaly, carcinoma of the thyroid (particularly follicular) and endometrium, and breast cancer. Occasional features include vascular malformations, lipomas, hamartomatous intestinal polyps, pigmented penile macules, Hashimoto thyroiditis (or other thyroid lesions), fibrocystic disease of the breast, uterine fibroids, and genitourinary malformations or tumors (especially renal cell carcinoma) (64).

Bannayan–Riley–Ruvalcaba syndrome is much rarer and has a classic triad of macrocephaly, intestinal polyposis, and genital lentiginosis (66). Birth length and weight are usually greater than the 97th percentile, although growth tends to normalize by midchildhood, with the final height within the normal adult range. Bone age is usually consistent with chronologic age, and macrocephaly persists into adulthood with normal ventricular size. Delayed gross motor development may be associated with a lipid storage myopathy, which appears to respond to treatment with carnitine. About 85% of patients with clinical features of Cowden syndrome (67) and 65% of patients with Bannayan–Riley–Ruvalcaba syndrome (67) have detectable *PTEN* gene mutations (68). *PTEN* is a tumor suppressor gene that functions as a dual-specificity phosphatase trafficking within and outside the nucleus (69,70). The nuclear functions of *PTEN* suggest it may be a genome stabilizer (71), autoregulating its activity through stabilization of p53, another tumor suppressor gene (72). Loss of the *PTEN* gene leads to the progression of brain tumors from benign to malignant secondary to the induction of angiogenesis (65,73).

**38.3.1.7 Megalencephaly Capillary Malformation Syndrome.** Moore et al. (74) initially proposed a sporadic distinct clinical syndrome of megalencephaly with capillary malformations (M-CAP) with features of cutis marmorata, nevus flammeus, CNS malformations with neurologic abnormalities, asymmetric growth,

**FIGURE 38-13** (A) One of dizygotic twins with megalecephaly capillary malformation syndrome at 12 and 40 months showing typical macrocephaly with capillary malformations fading and postnatally decreased growth in comparison with his twin sister. (B) Typical facial and limb features of macrocephaly capillary malformation syndrome at birth. The child experienced massive brain overgrowth with acquired tonsillar herniation requiring neurosurgical intervention and polymicrogyria resulting in seizures.

and macrocephaly (Figure 38-13). Thus macrocephaly-capillary malformation syndrome has come to be characterized clinically by prenatal-onset overgrowth with variable features of cerebral and somatic asymmetry, macrocephaly, neonatal hypotonia, cutaneous vascular malformations, and an abnormal neurocognitive profile

(75,76) and characteristic facial features. Conway et al. (77) analyzed the neurological features and underlying magnetic resonance imaging (MRI) findings in 17 cases of M-CAP syndrome and found that over half the patients have acquired cerebellar tonsillar herniation (versus congenital Chiari I malformation) with dilated

dural sinuses and ventriculomegaly secondary to rapid brain growth and progressive crowding of the posterior fossa often accompanied by (obstructive) hydrocephalus. This disorder is caused by post-zygotic mosaic mutations in *PIK3CA* (128).

### 38.3.1.8 Array CGH and Overgrowth Syndromes.

Array CGH has been found to be useful in the diagnosis of unknown overgrowth disorders (78). Among genetic causes of syndromic overgrowth, chromosomal deletions and duplications such as *dup(4)(p16.3)*, *dup(15)(q26qter)*, *del(9)(q22.32q22.33)*, *del(22)(q13)*, and *del(5)(q35)* have been identified, as well as a number of other rare copy number variations (CNVs), emphasizing the usefulness of this technique in unknown overgrowth disorders (78). Tatton-Brown et al. (79) reported a series of five patients with trisomy or tetrasomy of 15q, all of whom shared clinical features of overgrowth and learning difficulties with characteristic facial features including a long, thin face and prominent chin and nose. Three of these patients had renal anomalies including renal agenesis, horseshoe kidney, and hydronephrosis. Dolan et al. (80) reported a series of five patients with a Sotos-like syndrome and copy number variants within 19p13.13. The four patients with a deletion shared a phenotype of overgrowth with macrocephaly, ophthalmologic anomalies, gastrointestinal abnormalities, and learning disabilities. The patient with a duplication within 19p13.13 had microcephaly and short stature, with height affected more than weight. The smallest region of overlap a 311–340kb segment from base pair 12,793,474 to base pair 13,104,643 enriched with 16 genes including *MAST1*, *NFIX* and *CALR*. Malan et al. (81) demonstrated that mutations in *NFIX* resulted in the same phenotype, and that patients with Marshall–Smith syndrome also had mutations in *NFIX*. Marshall–Smith syndrome is an overgrowth syndrome characterized by accelerated osseous maturation; failure to thrive with limited life expectancy, usually secondary to respiratory dysfunction; hypotonia, moderate to severe developmental delay; and craniofacial anomalies including a prominent forehead, shallow orbits resulting in prominent eyes, blue sclere, depressed nasal bridge, and micrognathia (82,83). Diab et al. (84) underscored osseous fragility as an important aspect of this syndrome, and recent studies emphasize multiple nontraumatic fractures as significant clinical complication (82,85). Shaw et al. (83) found no copy number variants of clinical significance in a series of 12 patients with Marshall–Smith syndrome.

## 38.3.2 Segmental Overgrowth Disorders

Some disorders result in segmental or regional overgrowth (e.g. familial macrocephaly, congenital hemihyperplasia, Klippel–Trenaunay syndrome (KTS), Maffucci syndrome, Ollier disease, Patterson–David syndrome, and Proteus syndrome). Parameter-specific overgrowth disorders contrast with generalized overgrowth disorders

in that usually only a single growth parameter (e.g. weight) is affected. Examples of such disorders include those associated with obesity (e.g. Prader–Willi syndrome, Cohen syndrome, Börjeson–Forssman–Lehmann syndrome, Bardet–Biedle syndrome, and familial idiopathic obesity).

**38.3.2.1 Klippel–Trenaunay Syndrome.** KTS is a rare sporadic triad of congenital anomalies including cutaneous capillary malformations of a limb, venous malformations, and accompanying segmental hypertrophy of soft tissue and/or bone (86) or hypotrophy of a limb (usually lower limb) (87). Parkes–Weber syndrome (PWS) includes a clinically significant arteriovenous fistula (88). Ultrasound (Doppler) is used to distinguish KTS from PWS, as the prognosis and treatment are different, with magnetic resonance (MR) angiography as the gold standard for diagnosis to confirm involvement of superficial or deep venous involvement (87,89). Enoxaparin maintenance and recombinant coagulation factor VIIa have been successfully used to control potentially fatal consumptive coagulopathies resultant from the arteriovenous malformations (AVMs) of PWS (90).

**38.3.2.2 Proteus Syndrome.** Proteus syndrome consists of disproportionate or segmental overgrowth of limbs and macrocephaly associated with cranial hyperostoses, plantar hyperplasia; hemangiomas, lipomas or lymphangiomas, verrucous epidermal nevi, and variable psychomotor deficiency. Overgrowth and asymmetry are occasionally present at birth in 17.5% of cases (91). Among 205 reported cases of Proteus syndrome, which were reviewed to reassess the application of published diagnostic criteria, Turner et al. (91) concluded that there was overlap with other overgrowth syndromes. These authors emphasized that Proteus syndrome had asymmetric overgrowth with some asymmetry present from birth. Postnatal overgrowth of bone and soft tissue increases at a faster rate than the rest of the body (91), and this overgrowth tends to plateau at adolescence (92). Proteus seems to affect males more than females (1.9: 1) and has serious complications including premature death; scoliosis with megaspondyly; abnormalities of the CNS; ophthalmologic complications (especially strabismus); pulmonary, otolaryngologic, and dental complications; and elongation of the long bones with thinning (91). Most reports of Proteus suggest a sporadic disorder, and Happle (93) hypothesized that the cause of the syndrome was mosaicism for heterozygosity of an allele that would be lethal if present in all cells. Reported cases of monozygotic twins that are discordant for Proteus syndrome support the idea of postzygotic mosaicism (94). This disorder is caused by a post-zygotic activating mutation in *AKT1* (129).

**38.3.2.3 Hemihyperplasia-Lipomatosis and CLOVES Syndrome.** Hemihyperplasia-lipomatosis (HHML) syndrome and congenital lipomatous overgrowth, vascular malformations, and epidermal nevi (CLOVE) syndrome are segmental overgrowth syndromes that should

be considered in the differential diagnosis of Proteus syndrome. HHML syndrome was first delineated and distinguished from Proteus syndrome by Biesecker et al. (95) and is characterized by subcutaneous lipomatosis, asymmetric overgrowth (hemihyperplasia), and occasional vascular malformations. The hemihyperplasia is not as severe and progressive as is seen in PWS (95). HHML has been since reviewed by Dalal et al. (96) and Schulte et al. (97). Schulte et al. clarified the stark differences in the two syndromes as follows: unlike Proteus syndrome, lipomatosis is a main feature of HHML; likewise, the vascular malformations of HHML are capillary malformations without the involvement of the deep venous or lymphatic systems as seen in Proteus syndrome or KTS, and these are less susceptible to thrombosis (97). Some authors suggest that patients with HHML be screened for Wilms' tumor and hepatoblastoma (96,97).

CLOVE syndrome is an overgrowth syndrome characterized by congenital lipomatous overgrowth,

vascular malformations, and epidermal nevi. Sapp et al. (98) presented a series of seven patients previously diagnosed with proteus syndrome but with clinical features that deviated from the classic natural history and recognized diagnostic criteria. In addition to the features mentioned, these patients also shared varying degrees of scoliosis and bony structures that were enlarged but without the progressive enlargement seen in proteus syndrome (98). In this series of seven patients, several were noted to have plantar or palmar overgrowth with wrinkling of the skin. Both HHML and CLOVE syndrome are caused by post-zygotic activating mutations in *PIK3CA* (like M-CAP and fibroadipose hyperplasia (130,131)).

A few other important and distinctive prenatal-onset overgrowth syndromes are described in Table 38-2. Further analysis and study of these interesting syndromes should help shed light on the normal processes of human growth and morphogenesis.

**TABLE 38-2 Prenatal-Onset Overgrowth Syndromes**

Syndrome	Key Clinical Findings	Inheritance	Gene Testing
<b>Proportionate Syndromes</b>			
Beckwith–Wiedemann (130650)	Macroglossia, infraorbital creases, earlobe creases and pits, abdominal wall defects, neonatal hypoglycemia, visceromegaly, risk for abdominal neoplasms, hemi-hypertrophy, polyhydramnios, large placenta (54)	Sporadic, autosomal dominant	<i>H19</i> <i>LIT1</i> <i>CDKN1C/p57(KIP2)</i>
Perlman (267000)	Hypotonia, mental retardation, serration of upper alveolar ridge, nephromegaly, bilateral cortical hamartomas, nephroblastomatosis (124)	Autosomal recessive	
Sotos (117550)	Macrocephaly, dolichocephaly, down-slanted palpebral fissures, hypertelorism, prognathism, high narrow palate, premature eruption of teeth, large hands and feet, kyphoscoliosis, mental deficiency (38)	Sporadic, autosomal dominant	<i>NSD1</i> at 5q35
Weaver (277590)	Mental retardation, hypertonia, hoarse voice, macrocephaly, round face, ocular hypertelorism, down-slanted palpebral fissures, long philtrum, large ears, micrognathia, camptodactyly, thin deep-set nails, prominent fingertip pads (4)	Sporadic, autosomal dominant	<i>EZH2</i> at 7q35
Marshall–Smith (602535)	Accelerated linear growth and skeletal maturation, postnatal failure to thrive, hypotonia, developmental delay, structural brain anomalies, respiratory tract anomalies, recurrent pneumonia, pulmonary hypertension, dolichocephaly, coarse eyebrows, shallow orbits, blue sclere, upturned nose, low nasal bridge, small mandibular ramus, hypertrichosis, umbilical hernia, choanal atresia, omphalocele (82,83,85)	Sporadic, autosomal dominant	<i>NFIX</i> at 19p13.13
Bannayan–Riley–Ruv-alcaba (153480)	Delayed gross motor development, hypotonia, speech delay, mental deficiency, macrocephaly, prominent Schwalbe rings, prominent corneal nerves, pseudopapilledema, mesodermal hamartomas, pigmented penile macules, lipid storage myopathy (67)	Autosomal dominant	<i>PTEN</i> 10q23.31
Simpson–Golabi–Behmel (300209)/(312870)	Macrocephaly, ocular hypertelorism, short broad nose, large mouth, macroglossia, variable mental retardation, hypotonia, postaxial polydactyly of hands, nail hypoplasia, partial cutaneous syndactyly, cryptorchidism, supernumerary nipples, cardiac defects, gastrointestinal defects, large cystic kidneys (57)	X-linked recessive	Type 1 <i>CXORF5</i> Xp22.3-p21.2 Type 2 <i>GPC3</i> Xq26
Elejalde (256710)	Craniosynostosis, gross edema, short limbs, postaxial polydactyly, redundant neck skin, cystic renal dysplasia, congenital heart defect, spleen anomaly, micromelia (126)	Autosomal recessive	

*Continued*

**TABLE 38-2 Prenatal-Onset Overgrowth Syndromes—Cont'd**

Syndrome	Key Clinical Findings	Inheritance	Gene Testing
Cantu (239850)	Congenital hypertrichosis, neonatal macrosomia, macrocephaly, coarse facial features, broad nasal bridge, epicanthal folds, wide mouth, thick lips, and distinctive osteochondrodysplasia	Autosomal dominant	<i>ABCC9</i> at 12p12.1 (127)
19q13.13 Deletion (613638)	Proportional overgrowth, macrocephaly, frontal bossing, downslanting palpebral fissures with optic/ophthalmologic abnormalities like strabismus and/or optic nerve hypoplasia or atrophy, absent corpus callosum, autism (81)	Sporadic	<i>NFIX</i> deletion
<b>Disproportionate syndromes</b>			
Proteus (176920)	Regional overgrowth of hands and/or feet, asymmetry of limbs, plantar hyperplasia, hemangiomas, lipomas, lymphangiomas, varicosities, verrucous epidermal nevi, macrocephaly, cranial hyperostoses, long bone overgrowth, variable moderate mental deficiency (91,128)	Sporadic	Mosaic <i>AKT1</i>
Hemihyperplasia, lipomatosis, CLOVE		Sporadic	Mosaic <i>PIK3CA</i>
Megalencephaly capillary malformation syndrome (602501)	Megalencephaly, prenatal overgrowth, thickened subcutaneous tissue; over half of patients have acquired cerebellar tonsillar herniation (versus congenital Chiari I malformation) with dilated dural sinuses and ventriculomegaly secondary to rapid brain growth and progressive crowding of the posterior fossa (75–77)	Sporadic	Mosaic <i>PIK3CA</i>
Klippel–Trenaunay syndrome	Cutaneous capillary malformations of a limb, venous malformations, and accompanying segmental hypertrophy of soft tissue and/or bone (86)	Sporadic	

## ACKNOWLEDGMENTS

### Biographies

**David L Rimoin MD, PhD** During the final preparation of this book, we lost a major pioneer in the field of Medical Genetics: David L Rimoin, MD, PhD Dr. He died May 27th, 2012 following a diagnosis of pancreatic cancer only a few days earlier, having seen patients even on the Tuesday before he died. Dr Rimoin's achievements as Steven Spielberg Chair and Director of the Medical Genetics Institute at Cedars-Sinai, as the former Chairman of the Department of Pediatrics and Professor of Medicine and of Pediatrics at UCLA and founding director of the multi-campus UCLA Genetics Training Program, were profound. Children, adults and families from across the country and the world who turned to him for his medical expertise have lost a uniquely skilled and caring physician who was singularly devoted to their health and wellbeing. His medical contributions will continue to bring healing for generations—through the books he authored, his leadership and mentoring, the papers he presented, his lectures and speeches, and through the research that gave birth to lasting medical progress. We honor David Rimoin's passion for excellence, scholarship, innovation, his contributions to transformational medicine and his ceaseless kindness and integrity.

**John M Graham, Jr, MD, ScD** is a board-certified pediatrician and medical geneticist, with over 40 years of training and experience in clinical genetics, dysmorphology, clinical teratology, developmental disabilities, communicative disorders, and public health aspects of birth defects. He completed a pediatric internship and residency, as well as fellowships in developmental disabilities and dysmorphology and did original research on the teratogenic effects of alcohol, fetal constraint, and maternal hyperthermia. He is a steering committee member and co-founder of the David W Smith Workshop on Malformations and Morphogenesis and a Professor of Pediatrics (Step VIII) at UCLA School of Medicine, he teaches medical school courses on teratology and clinical genetics. Since 1988, he has been Director of Clinical Genetics and Dysmorphology at Cedars Sinai Medical Center in Los Angeles, and between 1981 and 1988, he held similar positions at Dartmouth Medical School in New Hampshire. He has contributed to a number of research efforts that have discovered the genes for a number of common conditions, which affect growth. These activities have resulted in new diagnostic tests for these conditions and contributed toward understanding the natural history and best modes of treatment for these disorders.

**Deepika D Burkardt, DO** is a categorical resident in her first year of training through the Wright State University General Surgery Residency Program. She completed her baccalaureate education through the College of Arts and Sciences and the College of Engineering at the University of Dayton. Her research efforts contributed to the synthesis and characterization of the crystal structure of novel inorganic chemical molecules with temperature sensitive luminescence.

She completed her medical education at Michigan State University College of Osteopathic Medicine. During her medical education, she was awarded the grant through the American Pediatric Society/Society for Pediatric Research Student Research Program to work at the Medical Genetics Institute at Cedars Sinai Medical Center under the mentorship of Dr David L Rimoin and Dr John M Graham, Jr where her research involved characterization of clinical features of patients with 1q24-q25 deletion syndrome along with involvement in several other projects related to skeletal dysplasias, limb defects, and seizures.

## Susceptibility and Response to Infection

Michael F Murray

### 39.1 INTRODUCTION

In every instance of human infection three forces intersect: the individual patient's genome, the microbial genome(s), and environmental factors. These vectors meet, and each influences the clinical outcome, and a change in any one of these three forces can alter the outcome. In 2011, the United States Center for Disease Control and Prevention reported an unfortunate case that serves to demonstrate the genome vs. genome vs. environment nature of human infection (1). The case report gave details of a fatal laboratory-acquired infection with an "avirulent strain" of *Yersinia pestis*, the causative agent of plague. The attenuated *Yersinia* strain, known as KIM D27, has an iron acquisition defect associated with a 102 kb deletion of the *pgm* locus and is thus rendered nonvirulent to most human hosts (2). This strain has been used in laboratory research for many years, without high-level precautions because of its attenuated nature. However, in this case, the laboratory worker appears to have been rendered susceptible to this strain of *Y. pestis* because of his state of clinical iron overload. The worker's iron overload state and hemochromatosis (*HFE* C282Y homozygous) were diagnosed postmortem. It appears that the change in the human genome at *HFE* set in motion events that ultimately allowed a *Y. pestis* with a *pgm* deletion to become pathogenic in the setting of an iron-rich host following exposure in the unique environment of the research laboratory.

While this case report example demonstrates the concept in a unique instance, the genome vs. genome vs. environment interaction can play out over a time course of many human generations as common deadly infections, such as malaria, sculpt the human genome in chronically exposed populations (3). Thus, infection is a clear example in which nonhuman genomes exert influence on human health.

It has been suggested that microbial infection likely represents a primary driving force of natural selection in humans, particularly in the past five thousand years (4). In the spirit of his day, Haldane (5) suggested that

"the abolition of infectious diseases, which is now a possibility, and may be a reality in 50 years, should lead not only to an immediate improvement in human physique, but to a progressive improvement through many centuries." We are now more than 50 years hence, and it has become clear that despite the optimism associated with the antibiotic revolution of the mid-twentieth century, both new (e.g. human immunodeficiency virus) and old (e.g. malaria) infections are continuing to exert substantial selective pressure on human populations (6). Although infectious diseases will likely persist because of microbial and host evolution, a detailed understanding of host genetic susceptibility and response to infection will facilitate improvements in existing therapies and the development of new therapies.

As in other areas of clinical medicine, information regarding the impact of human genetics on infectious diseases is rapidly expanding beyond our classical appreciation of this interaction. A classical notion of genetic susceptibility to infection is typified by many of the primary immunodeficiency states, where monogenic mutations produce broad susceptibility to infection. Instead, this chapter will examine a wide range of human polymorphisms and mutations that alter susceptibility to infection, often by action outside of what is typically considered the immune system. In many cases, the altered susceptibility results from an altered dynamic phenotype, i.e. a phenotype appreciated in the context of an infection, although otherwise unrecognized.

The term "genetic susceptibility" as used in this chapter and in the referenced literature has several different connotations that are worth delineating. There are instances of alterations in "susceptibility" to (1) acute infection, (2) chronic infection, and (3) the morbidity and mortality associated with infection. There are only three known instances in which genetic resistance to acute infection is essentially complete (Figure 39-1). The special circumstances shared in these instances of "complete resistance" are (1) an infecting microbe whose life cycle requires an intracellular stage within an obligate human cell type, (2) a cell surface protein that

**FIGURE 39-1** Instances in which genetic resistance to acute infection is essentially complete.

acts as a cellular receptor for the microbe and whose lack of expression can be tolerated by the human host, (3) the existence of a genetic variant that leads to a null obligate cell (i.e. null for the specific cell surface protein in question). The details of the gene variants for the examples of “complete resistance” to specific infection (that are outlined in Figure 39-1) are included in the text of this chapter. Given a general lack of dispensability among human surface proteins, the mechanism for “complete resistance” exemplified here seems unlikely to have broad applicability. Instead, it is reasonable to expect that most instances of host resistance to the establishment of acute infection will ultimately prove to be cases of “relative resistance.”

The chapter is organized such that the key principle of heterozygous advantage is examined first, the contribution of recent genome-wide association studies (GWAS) to our current understanding of the topic next, and then finally a look at the knowledge base associated with individual genes, organized by location of the gene product in the context of the cell. The categories of cellular locations are cell surface proteins, intracellular proteins, and extracellular proteins.

### 39.2 HETEROZYGOUS ADVANTAGE AND HOMOZYGOUS DISADVANTAGE

The notion of heterozygous advantage with respect to infectious disease is typified by the example of sickle-cell disease and malaria (7). It is important to note that under the selective pressure of malaria there is the complementary phenomenon of homozygous disadvantage, such that both the person homozygous for the normal  $\beta$ -globin allele and the person homozygous for the mutant  $\beta$ -globin allele are at a disadvantage despite the fact that the  $\beta$ -globin<sup>S</sup>/ $\beta$ -globin<sup>S</sup> genotype offers additional antimalarial advantage compared to the heterozygote. With regard to human leukocyte antigen (HLA) heterozygosity there is evidence for advantages (see HLA discussion later). However, while this phenomenon has been suggested for other common recessive alleles, such as *CFTR*  $\Delta$ F508, a clear proof has been somewhat elusive (8).

In 2010, an important new example of heterozygous advantage with respect to selective pressure of infection in Africa was recognized. A link was made between an

unlikely infectious-disease-associated gene, apoprotein L1 (*APOL1*), and an increased risk of renal disease in African-Americans (9). Researchers went on to prove that two common variant alleles of this gene (i.e. *APOL1* G1 or *APOL1* G2), which are present in West African populations, are associated with protection against African trypanosomiasis, but when found in the homozygous state (G1/G1 or G2/G2) appear to be a risk for renal failure. Like the sickle hemoglobin–malaria situation, the scenario of *APOL1*-trypanosomiasis appears to be one where away from the selective pressure associated with infection (e.g. North America), there is a genetic disadvantage but no clear advantage to carrying the *APOL1* alleles. Unlike the sickle cell–malaria scenario, the homozygous disadvantage of the variants do not likely exert pressure on reproductive fitness in Africa since renal disease typically occurs later in life, beyond the life expectancy of most native Africans.

The work of Lyons and colleagues (10) suggests that more examples may exist, including examples of homozygous disadvantage for invasive bacterial infection. In their study of microsatellite markers in African children who died of invasive bacterial infection and controls they found that homozygosity at a relatively small sample of markers was associated with significant increases in the odds ratio for mortality due to invasive bacteria, these markers segregated differently in some cases based on Gram-positive vs. Gram negative bacteria. The most significant odds ratio (40.7; 95% confidence interval (CI), 4.28–387) was observed for Gram-negative infection in those children who were homozygous for both a site at 7q31 (D7S486) as well as a second site at 16p13.3 (D16S423). The mapping of the pathogenic genetic variants linked to this recessive disease risk has not yet been reported.

### 39.3 GENOME-WIDE ASSOCIATION STUDIES AND HUMAN INFECTION

A number of studies have been published looking for genome-wide associations between human infectious diseases and human single-nucleotide polymorphisms (SNPs). As with GWAS in other human diseases, these findings have the potential to lead to the discovery of new and important biological pathways for understanding disease pathogenesis. Of 910 GWAS publications listed on the NHGRI Catalog of Published Genome-Wide Association Studies (11), there are 21 that examine human infection and associated morbidity. The infections examined include human immunodeficiency virus 1 (HIV-1), hepatitis B virus (HBV), hepatitis C virus (HCV), *Neisseria meningitidis*, *Mycobacterium tuberculosis*, *Mycobacterium lepra*, and bovine spongiform encephalopathy (BSE) prions. Published work has also been carried out on other infections including *Plasmodium falciparum*, the causative agent of human malaria. In addition to the many new research leads,

these studies confirmed two long coding variants as associated with altered disease susceptibility; these are (1) the association of the HBB sickle variant (rs334) with malaria resistance (12) and (2) the association of the PRNP missense variant (rs1799990) with susceptibility to prion disease (13).

A GWAS on susceptibility to leprosy was carried out within a Chinese population by Zhang and colleagues (14). Associations with SNPs implicated four genes (*C13orf31*, *NOD2*, *TNFSF15*, *RIPK2*), which are also linked to inflammatory bowel disease. The strongest association was with an SNP that confers a missense change in *C13orf31*, a gene of unknown function; this same SNP has also been associated with Crohn disease (15). This variant of *C13orf31* encodes an amino acid substitution (Ile254Val) and has also been associated with leprosy susceptibility in Indian and West African populations (16). In this way, the “unbiased” GWAS approaches bring back into focus a long-speculated connection between mycobacterium susceptibility and Crohn disease susceptibility (17), although the fine details of both of these pathways remain to be worked out.

Of the dozens of additional associations in the GWAS that are listed in the NHGRI catalog (11), several SNPs are within genes that seem at this time to have a greater likelihood than others of being the causative variant in the association. First, there are two missense mutations in the *HCP5* (HLA complex P5) gene within the human major histocompatibility complex (MHC) at 6p21.33, in particular the SNP rs2395029, which has been associated with the control of HIV-1 viremia and the rate of progression to AIDS in three different studies (18–20). Second, there is an SNP conferring a nonsense stop to *ZNF229* (rs1434579), which is associated with tuberculosis susceptibility (21). Last, there are three separate associations between 3′ untranslated region (UTR) SNPs and infectious diseases; these of course raise the possibility for alterations in the modulation of the genes via microRNAs. The 3′ UTR SNPs associations include one with chronic HBV infection, *HLADPB1* rs9277535 (22), and two with HIV-1, *TRIM10* rs9468692 (18) and *ZNRD1* rs8321 (19).

## 39.4 CELL SURFACE PROTEINS

### 39.4.1 The ABO Blood Group Gene (ABO) and the Fucosyltransferase Genes (*FUT1*, *FUT2*, and *FUT3*)

Four genes coding for five different glycosyltransferases determine three polymorphic traits: classical “blood group” type, “secretor” status, and Lewis antigens. The monogenic basis of the ABO blood groups was predicted by Bernstein in the first half of the twentieth century and then demonstrated by Yamamoto and colleagues more than 50 years later to be encoded by the polymorphic single gene, known as *ABO*, located in the long arm of

chromosome 9 (9q34) (23,24). What were functionally characterized as separate transferases arising from this locus are in fact variants of the same protein. The alpha 1–3-N-actylgalactosaminyltransferase (transferase A) and the alpha 1–3-galactosyltransferase (transferase B) are differentiated by four amino acid residues. The transferases act upon the “H” antigen to form the oligosaccharide blood group antigens “A” and “B.” Frameshift mutations in the same gene result in the absence of any enzyme function in some individuals. In the absence of transferase activity, the unmodified “H” antigen defines the “O” phenotype. The enzymatic activity of fucosyltransferase 1 (*FUT1*) provides the oligosaccharide substrate for the ABO glycosyltransferases by creating the H antigen. Mutations in *FUT1*, which lead to the absence of the H antigen, exist but have no specific link to altered infectious diseases susceptibility. ABH antigen types are codominant in their expression (25).

ABH antigens have a wide distribution in addition to erythrocytes, including vascular endothelial cells and intestinal, cervical, urothelial, and mammary epithelial cells. These antigens can also be found in the body fluids of persons with inherited FUT 2 activity—i.e. positive “secretor” status (25). The nonerythrocytic distribution of antigens appears to account for many reported infectious disease associations.

The genes encoding FUT 1 and FUT 2 lie in the long arm of chromosome 19 (19q13.3). Individuals with the nonsecretor phenotype are homozygous for mutations associated with the nonfunctional FUT 2 enzyme, thereby giving the nonsecretor status an autosomal recessive inheritance pattern. In an American study, homozygous alleles for a nonsense mutation were found at codon 143 of *FUT2* in 20% of persons tested (26), while different mutations resulting in a nonfunctional enzyme have been found in other populations (27). Secretor status is associated with FUT 2 activity and results in secreted ABH antigens in saliva, plasma, urine, milk, and feces.

Since the first reported associations of ABO blood groups to disease states, numerous attempts have linked infectious diseases with specific ABH antigens and secretor status, and this extensive literature has been reviewed elsewhere (28,29). It appears that ABH antigens and secretor status influence susceptibility to infectious diseases in most cases by acting at mucosal sites of microbial exposure. The mucosal sites involved include the oropharyngeal, respiratory, gastrointestinal, and genitourinary tracts. Three common agents of bacterial meningitis gain access to the central nervous system via the upper respiratory tract mucosa and are linked to nonsecretor status (30,31). An association between the presence of the O blood group and cholera susceptibility has been demonstrated in multiple studies (32,33). In a Senegalese population, women who were exposed to HIV-1-positive heterosexual partners appeared to be at increased risk of infection if they were secretors, suggesting that the presence of ABH antigens in vaginal secretions increased

the risk of HIV-1 transmission (34). A reported association between resistance to infection by some strains of the Norwalk virus (a common cause of gastroenteritis) and blood group B is consistent with the concept of these antigens influencing infectious disease outcomes at mucosal surfaces (35). However, reported associations of blood group antigens with malaria have recently been described (36,37), and this suggests a link between an erythrocyte antigen and intraerythrocytic infection by *P. falciparum* separate from any mucosal surface.

A third fucosyltransferase gene at locus 19q13.3 (i.e. *FUT3*) determines the expression of Lewis antigen. Although the results have been debated, studies have linked Lewis antigen status to *Helicobacter pylori* infection in the gastric antrum (38) and gram-negative urinary tract infections. Expression of particular Lewis antigens by gastric epithelial cells may enhance colonization and infection by *H. pylori*. In addition, *H. pylori* expresses microbial “Lewis antigen,” although the precise role of this microbial lipopolysaccharide (LPS) is unclear (39)

### 39.4.2 Alpha 1,4-Galactosyltransferase (A4GALT)

Erythrocyte P antigens have been characterized by serologic studies to yield at least five surface antigenic variants. P antigens are present in multiple cell types, including lymphocytes, in which they comprise part of the Gb3/CD77 molecule (40). The P null (or p) phenotype is quite rare in the general population. However, in northern Sweden there is a carrier rate of up to 2% for the null phenotype in some population groups (41). In this group, persons who are homozygous for a point mutation in the *A4GALT* gene in chromosome 22q13.2 are phenotypically P null (42). These individuals lack active “P<sup>K</sup> synthase” activity, that is, the specific galactosyltransferase activity required to convert lactosylceramide to globotriaosylceramide (42). All the *A4GALT* alleles reported to date in P null individuals from Sweden and Japan have mutations within the coding sequence (42–44), in contrast to the regulatory sequence change leading to FY-null erythrocytes.

Parvovirus B19 is a ubiquitous human pathogen infecting most individuals around the world, with a seroprevalence of up to 90% in some adult populations (45). It causes a range of diseases including erythema infectiosum, hydrops fetalis, and transient aplastic anemia (46). Since P antigen is the erythrocyte receptor for human parvovirus B19, P null individuals are uniquely resistant to parvovirus B19 infection (47) (Figure 39-1). However, this rare phenotype does not appear to afford a significant selective advantage, and it is believed that the elevated P null frequencies in northern Sweden result from founder effect and genetic drift (48). This membrane protein also acts as a receptor molecule for Shiga-like toxins from *Escherichia coli* O157, the microbe that induces hemolytic uremic syndrome. However, there is

no research to date linking *A4GALT* genotypic variations and human clinical phenotypes in the setting of this bacteria (49).

### 39.4.3 Chemokine, CC Motif, Receptor 5 (CCR5) and Chemokine, CC Motif, Receptor 2 (CCR2)

Chemokine receptor 5 (CCR5) serves as a natural receptor for  $\beta$ -chemokines including CCL5, CCL3, and CCL3L1. CCR5 also acts as a viral coreceptor for macrophage tropic (M-tropic) strains of HIV-1 (50,51). This receptor is encoded in 3p21, and the gene product is expressed on the cell surface of macrophages.

A 32-base-pair deletion (nucleotides 794 to 825) in CCR5 (CCR5  $\Delta$ 32) (52) results in the loss of receptor expression on cell surfaces; this confers resistance to HIV-1 infection in the homozygous state (53) (Figure 39-1) and slower progression to AIDS in the heterozygous state (54). Meta-analysis revealed a consistently lower serum viral load associated with the presence of the CCR5  $\Delta$ 32 mutation (55). In one study of 334 men in Amsterdam, wild-type CCR5 was associated with an increased relative risk for HIV-1 disease progression (by a factor of 2.5) compared to heterozygous CCR5  $\Delta$ 32 (56).

A survey involving 4166 individuals suggested that CCR5  $\Delta$ 32 was absent in African, American Indian, and East Asian populations but present in 0–14% of Eurasian groups. Stephens and colleagues (57) estimated that the CCR5  $\Delta$ 32 mutation arose approximately 700 years ago (range, 275–1875). It has been suggested that a strong positive selective pressure, such as an infection via the CCR5 coreceptor, drove a recently increased gene frequency. Since HIV-1 is estimated to have infected human populations only after the 1940s (58), CCR5  $\Delta$ 32 is postulated to provide protection against at least one other as yet unidentified microbe. While the loss of a functional receptor associated with this allele appears to be inconsequential to the health of most heterozygotes, one study has suggested an associated increased risk of primary sclerosing cholangitis (59).

Two other protective polymorphisms and one deleterious polymorphism have been associated with CCR5 and HIV-1 infection. Homozygous individuals with a point mutation at position –502 relative to the transcription initiation site had delayed onset (3.8 years) of AIDS when compared to individuals with wild-type CCR5 (60). This variant was very common (43–68%) compared to either CCR5  $\Delta$ 32 or the third protective variant, known as the m303 mutation. While m303 occurred in less than 2% of individuals in the surveyed population, it was discovered in a multiply exposed HIV-1-negative individual. The compound heterozygous state with m303 and CCR5  $\Delta$ 32 in one patient conferred complete in vitro resistance to HIV-1 (61). In contrast, Martin and colleagues (62) attributed rapid HIV-1 disease progression (i.e.

development of AIDS in less than or equal to 3.5 years) to homozygosity for a polymorphism in the *CCR5* promoter region (*CCR5* P1). Homozygosity of *CCR5* P1 occurred in 12.7% of Caucasian Americans and 6.7% of African-Americans.

Chemokine receptor 2 (*CCR2*) is encoded at gene locus 3p21, in close proximity to *CCR5*. A point mutation causing the neutral substitution of isoleucine for valine (V641) has been studied as a potential AIDS susceptibility polymorphism. *CCR2* V641 was present in 10% of Caucasian Americans, 15% of African-Americans, 17% of Hispanic Americans, and 25% of Asian-Americans in one large study (63). Wild-type *CCR2* is in strong linkage disequilibrium with *CCR5*  $\Delta$ 32, which facilitates examination of distinct effects of each of the two polymorphisms (63). *CCR2* V641 is not associated with differences in HIV infectivity, but it is associated with a 2–4-year delay in the onset of AIDS in HIV-infected persons (63).

*CCR2* is unlikely to be a primary cellular coreceptor for HIV-1 when compared to *CCR5* and *CXCR4*. Evidence suggests that the *CCR2* V641 mutation could inhibit HIV-1 indirectly, through the desensitization of *CCR5* and *CXCR4* receptors to their normal ligand responses (64). However, the worldwide presence of exceptionally strong linkage disequilibrium between *CCR2* V641 and *CCR5* promoter polymorphism (*CCR5* 59635T), and the fact that V641 encodes a neutral amino acid change in a transmembrane domain, has led to speculation that *CCR2* V641 could be a marker for a different biologically significant mutation (65).

#### 39.4.4 CD14 Antigen (CD14)

The CD14 gene locus is at 5q31.1. CD14 is a surface protein on macrophages that has been implicated in bacterial LPS signaling (66). An SNP in the promoter (C-159T) has been associated with enhanced transcriptional activity for the gene (67). Homozygosity for CD14 159T was associated with Gram-negative infection and an increased prevalence of positive bacterial cultures in critically ill adults (68). The same promoter polymorphism has also been associated with chronic infection of peripheral blood monocytes with *Chlamydia pneumonia* (69). The notion that chronic *C. pneumonia* infection may be a risk factor for coronary artery disease, while controversial, is indirectly supported in this context by other studies that have linked this promoter polymorphism with myocardial infarction in a patient group that was considered “low risk” for atherosclerosis when assessed by a standard risk profile (70).

#### 39.4.5 Cystic Fibrosis Transmembrane Conductance Regulator

The cystic fibrosis transmembrane conductance regulator (CFTR) functions as a cytoplasmic membrane

chloride channel and ion transport regulatory protein, and its gene, *CFTR*, has been localized in chromosome 7q31. Cystic fibrosis (CF) is an autosomal recessive disease associated with the inheritance of mutant *CFTR* in both homozygous or compound heterozygote fashion (Chapter 58), and the increased susceptibility to infection associated with the CF phenotype is limited to the sinopulmonary tract.

*CFTR* mutations result in defects in the internalization and clearing of *Pseudomonas aeruginosa* in the respiratory tract. In the absence of normal clearing by the respiratory epithelial cells, *P. aeruginosa* infection occurs in 75–90% of patients with CF. Notably, *Pseudomonas* strains in the respiratory tract of CF patients adapt to this host alteration by transitioning from isolates with smooth LPS and no extracellular mucoid exopolysaccharide to isolates with rough LPS and mucoid hyperexpression. The microbial advantage gained by this adaptation has not been fully elucidated (71). Wild-type *CFTR* also serves as a receptor for *Salmonella typhi* on gastrointestinal epithelial cells (72). Mutant *CFTR* results in diminished translocation of *S. typhi* across the mucosal barrier; this diminished invasiveness of *Salmonella* is postulated to represent the heterozygous advantage of the carrier state, which allowed the carrier frequency of mutated *CFTR* to reach 4% in some Caucasian populations. A recent study also suggested that a disproportionate number of cases of chronic sinusitis might be associated with CF carrier status, i.e. a mutation in just one *CFTR* allele (73).

There is growing evidence that variations in other “modifying” genes act in concert with *CFTR* to influence infectious disease susceptibility. Genes encoding variants of MBL2 have been associated with increased liability for infection, decreased pulmonary function, and decreased survival time (74,75). DeRose and colleagues recently reported on a cohort of CF patients with a matched *CFTR* genotype ( $\Delta$ F508/ $\Delta$ F508) in whom allelic variants of *FCGR2A* were significantly associated with an altered risk of acquiring chronic *P. aeruginosa* infection (76).

The clinical use of the aminoglycoside antibiotic gentamicin to induce translational read through of stop mutations in *CFTR* resulting in expression of functional *CFTR* has been reported (77). A small molecular therapy based on this observation is in clinical trials (78); however, since only a minority of CF patients has *CFTR* alleles with stop mutations, the practical utility of this intervention may be quite limited.

#### 39.4.6 Chemokine, CX3C Motif, Receptor 1 (CX3CR1)

The chemokine receptor CX3CR1 is a leukocyte chemotactic and adhesion receptor for the chemokine CX3CL1 (formerly known as fractalkine) (79). The gene for this receptor lies in the short arm of chromosome 3 (3p21). In addition to being a receptor for CX3CL1, this cell

surface molecule also acts as a coreceptor for HIV-1. HIV-1-infected adult patients homozygous for a polymorphic allele including two point mutations (V249I and T280M) were statistically more likely to have rapid progression of disease relative to those with the wild-type gene (80). Although this allele had a frequency of 13.5% in the uninfected French population studied and ranged from 12.6 to 19.8 % in three infected cohorts examined, the polymorphism was not detected in the non-Caucasian populations tested (80). Homozygosity for the I249 allele has also been linked with HIV-1 progression in children (81). Interestingly, both M280 and I249 have now also been associated with atherosclerotic disease (82,83).

### 39.4.7 Chemokine, CXC Motif, Receptor 4 (CXCR4)

CXCR4 is a chemokine receptor for CXCL12 (which is also known as SDF1); *CXCR4* is at 2q21. The gene product is a seven transmembrane receptor protein that is highly expressed on many cell surfaces including breast cancer cells (84). Although CXCR4 is also a coreceptor for HIV-1, there have not been any associations to date between polymorphisms in this gene and this retrovirus. A recent report, however, has linked mutations in this gene with an autosomal dominant immunodeficiency syndrome known as WHIM syndrome (OMIM 193670); this syndrome is characterized by recurrent bacterial sinopulmonary infection and widespread chronic human papilloma virus (HPV) infection (85). The authors point out that their observations linking this gene and this syndrome suggest an association between CXCR4 and the normal control of HPV.

### 39.4.8 Duffy Blood Group (FY)

Chromosome 1q22–23 includes *FY*, which encodes the glycoprotein (GP) “duffy blood group” antigen or “duffy antigen receptor for chemokines” (DARC). This antigen has had many names in the literature including Duffy antigen, FY antigen, and glycoprotein D (GPD). DARC binds interleukin-8 (IL-8), CXCL1, CCL5, and CCL2 (86). Vascular endothelial cell expression of DARC may underlie its primary chemokine receptor function (87).

DARC was first described in a patient named Duffy with alloantibodies against this GP (88). Three common alleles exist in US populations, i.e. *FY*\*A, *FY*\*B, and *FY*\*O (also known as Duffy null or *FY*\*B<sup>ES</sup>). These codominant alleles lead to four serologic red blood cell phenotypes i.e. Fy (a+b–), Fy (a–b+), Fy (a+b+), and Fy (a–b–). The Fy (a–b–) phenotype, which is genotypically homozygous for the *FY*\*O allele, is common in African-Americans and West Africans (89). The coding sequence for *FY*\*B and *FY*\*O is identical (90). An SNP in the *FY*\*B 5'UTR leads to disruption of the GATA binding

site for erythroid transcription factor (91). Hence, *FY*\*O is the “erythroid silent” allele (*FY*\*B<sup>ES</sup>) but is present in a typical distribution on nonerythroid cells.

*Plasmodium vivax*, the second most common cause of human malaria, is incapable of establishing infection in individuals homozygous for *FY*\*O (92). Thus, the *FY*\*O allele is an example of a human polymorphism that prevents a specific microbial infection (Figure 39-1). In a remarkable demonstration of the bidirectional selective pressure in human–microbial populations, the region of West Africa where *FY*\*O predominates is free of *P. vivax* infection, thereby making this region unique within its latitude (93).

### 39.4.9 FC Fragment of IgG, Low Affinity IIA, Receptor (FCGR2A)

FCGR2A is a cell surface receptor that was formerly known as CD32. The gene locus is at 1q23; the gene product is expressed on a wide variety of cell types, and it mediates multiple cell-type specific functions including phagocytosis, release of inflammatory mediators, and clearance of immune complexes (76). A polymorphism of the gene has been reported, in which a single-nucleotide change results in either arginine (R) or histidine (H) at amino acid 131 of the mature protein. This polymorphism has been associated with both noninfectious and infectious risks, including an altered risk for nephritis in the setting of lupus (94). *P. aeruginosa* infection in the setting of CF (76), increased risk of respiratory tract infections (95,96), and susceptibility to perinatal infection in infants of HIV-1-infected mothers (97).

### 39.4.10 Human Leukocyte Antigen (HLA) Genes

The HLA genes display a high degree of polymorphism and serve as a model for human genes in an apparent state of coevolution with infecting microbes. They are encoded in the short arm of chromosome 6 (6p21.3) and have been implicated as a modulating influence in a large number of infections (Table 39-1). The HLA system, which is part of the human MHC, has been concisely reviewed elsewhere (98,99). MHC proteins, encoded by class Ia genes including *HLA-A*, *HLA-B*, and *HLA-C*, are expressed on most nucleated cells. The class II genes, also known as *HLA-D*, are designated with a three-letter code (e.g. *HLA-DRB*), which indicates class (D), family (M, O, P, Q, or R), and chain (A or B). Proteins encoded by class II genes are expressed on leukocytes (both B and T), macrophages, dendritic cells, and thymus cells. In both classes, numbers are assigned to each allele; this nomenclature is different for sequence-defined and for serologically defined variants. An asterisk followed by a number indicates a genotypic variant (e.g. *HLA-A*\*0101), while a number without an asterisk represents a serologic variant (e.g. *HLA-A*1) (100). An online

TABLE 39-1 HLA Class Ia and Class II Associated Diseases

Microbe	Type of Organism	Disease(s)	Class	References
Human T-lymphotropic virus-1 (HTLV-1)	RNA virus	Myelopathy	Ia	(269)
Human immunodeficiency virus-1 (HIV-1)	RNA virus	AIDS	Ia and II	(271) (65) (276)
Hepatitis C virus	RNA virus	Viremia	II	(114)
		Mixed cryoglobulinemia	Ia and II	(124)

<i>Paracoccidioides</i> spp.	Fungus	Mycosis	Ia	(273)
<i>Fonsecaea pedrosoi</i>	Fungus	Chromoblastomycosis	Ia	(285)
<i>Trichosporon</i> spp.	Fungus	Hypersensitivity pneumonitis	II	(258)
<i>Cryptococcus neoformans</i>	Fungus	Meningitis	Ia	(286)

“Immunogenetics (IMGT) HLA Sequence Database” is available at <<http://www.ebi.ac.uk/imgt/hla>> (101).

The class II molecules are heterodimers, which allows for alpha/beta matching within and between families (e.g. DRA and DQB), and result in approximately 12 different class II antigens available on the cell surfaces of heterozygotes (102). Heterozygotes also express six different class Ia antigens. Owing to codominant expression, homozygotes likely express half as many different surface antigens as heterozygotes. Recombination within the MHC region allows for individuals who are

homozygous for one locus or for an entire haplotype. Thus, there is a range of expressed HLA types within human populations.

HLAs are pivotal in the processing and presentation of microbial antigens to the human immune system. Inefficient or failed peptide presentation can result in disadvantages for the host when combating infection. This was recently demonstrated in a cohort of HIV-infected patients, where a single amino acid change in a region critical to peptide presentation was associated with significant risk of rapid disease progression (103).

Twenty-one highly polymorphic HLA genes with more than 2000 recognized HLA alleles have been described (<http://www.ebi.ac.uk/imgt/hla>). This diversity is as yet unmatched elsewhere in the human genome. Infections may represent a driving force of HLA genetic diversity. Proposed mechanisms of infection-driven diversity include overdominant selection (or heterozygous advantage) and frequency-dependent selection (104). The overdominant selection hypothesis holds that the individual with the most available HLA types will be best suited to handle the largest variety of microbial antigens. The frequency-dependent selection hypothesis suggests that in a population, the selective force of the microbe on the host will favor uncommon HLAs to which the microbe has not yet adapted. Both mechanisms favor diversity, and they are not mutually exclusive processes.

The overdominant selection hypothesis has been supported both in principle (105) and with empirical data of specific infectious diseases. Heterozygous advantage has been demonstrated in three chronic viral infections: HPV, HBV, and HIV-1 (106–108). On the other hand, although not predicted by those seeking to explain HLA diversity, homozygous advantage has also been demonstrated (7,109). Homozygous advantage in the context of a specific microbial infection can be explained by increased numbers of a “preferred” HLA protein that is capable of superior presentation of specific “constant” microbial peptide antigens.

Frequency-dependent selection can be invoked to explain variations in the frequency of HLA-B53 in Africa. This HLA is associated with protection against severe malaria in studies performed in Gambia (7). While population frequencies in black South Africans are only about 2%, class Ia antigen reaches frequencies of up to 40% in malaria-prone regions of West Africa. HLA-B53 is extremely rare or altogether absent in most non-African populations. Malaria appears to have acted as a directional selective force on local populations for 10,000 years. Plasmodial infections may have increased the frequency of HLA-B53 to levels greater than expected by genetic drift, as observed currently in West Africa (110).

Coevolution of humans and microbes is an important concept in the study of HLA and infection. An African study of malaria peptides and HLA-B35 found evidence for bidirectional effects of human and parasitic alleles (111). Although observations such as this are still relatively rare, the opportunity for important observations in this area will grow with acquisition of human and microbial sequence data. For example, the use of a HIV-1 sequence database together with knowledge of HLA peptide constraints and epidemiological data on HLA influence on outcomes has allowed one group to correlate protective HLA types with their anticipated capacity to bind the observed range of motifs in the highly mutable HIV-1 (112).

Specific HLA alleles have been associated with cancers linked with chronic viral infections. HLA associations have been reported for several viral infections, including HBV, HCV, HPV, and Epstein–Barr virus (EBV). Hepatocellular carcinoma is associated with persistent viremia in both HBV and HCV, and while there is little direct evidence at this point for HLA associations with hepatocellular carcinoma, HLA associations have been reported with persistent viremia in chronic HBV or HCV infection (113,114). HPV is a primary etiologic factor in the development of cervical carcinoma (115), and HLA associations have been documented in cervical dysplasia and cervical carcinoma (116). Undifferentiated nasopharyngeal carcinoma is tightly linked with chronic EBV infection and has been associated with specific HLA antigens (117).

The exclusive application of serology-based (phenotypic) rather than sequence-defined (genotypic) HLAs represents a significant limitation with earlier HLA association studies. HLA genotyping emerged in the 1990s and yielded relatively greater specificity in HLA association studies. HLA antigens defined by serotyping represent phenotypes that have been useful with particular rheumatologic disease associations (e.g. HLA-B27 and ankylosing spondylitis; Chapter 78), but relatively nonspecific results obtained by such studies may be confounding. An example of the relative specificity of HLA genotyping and its ability to clarify otherwise contradictory data was demonstrated in the case of HLA-DR1 and HIV-1 infection. One group reported DR1 to be protective (118), while another group’s data suggested that DR1 increased risk for progression (119). In a third report, it was found that *HLA-DRB1\*0101* was associated with a risk for progression and *HLA-DRB1\*0102* appeared to be protective against progression; both these alleles are serologically grouped as HLA-DR1 (120). It can be expected that most studies will use genotypically defined alleles alone or in combination with serologically defined groups in the future.

Linkage disequilibrium between HLA and non-HLA genes within the MHC region may confound results obtained in the study of HLA and infection. HLA haplotypes, such as the “8.1 haplotype” (A1, B8, DR3) (121), have been associated with several infectious diseases; the association of the 8.1 haplotype with HIV-1 (122,123), HCV (124), or herpes simplex virus (HSV) (125) infection may be due to individual HLA loci, the combination of HLA loci, or the non-HLA genes carried with the MHC. Non-HLA effector genes closely linked with HLA loci include tumor necrosis factor (TNF), lymphotoxin A (LTA), transporters associated with antigen processing (TAP), and complement component genes.

The prevalence and cumulative effects of multiple infections, each with a different selective influence and occurring within the same human population must be considered when studying the role of HLA antigens in

infection. Most studies have attempted to evaluate the influence of a single microbe with the HLAs of a discrete human population. However, human populations are subject to numerous microbial infections that occur sequentially and concomitantly during a lifetime. This multipronged attack may favor HLA diversity, although it makes isolating the effects of one infection from another in a given population challenging. Insight may be gained into this situation by reexamining the interaction between HLA and two infections: one that exerts strong directional selection and one that does not exert obvious selective pressure. In the study referred to previously, HLA protection from malaria was associated with both class Ia and class II antigens (7). Howard (110) predicted that increases in specific HLA frequencies in response to malaria would ultimately result in either a counter-response from *P. falciparum* or the opportunity for another pathogen to “take advantage.” Three years later, the *DQB1*\*0501 allele, which together with HLA-B53 had been associated with protection against severe malaria, was linked with susceptibility to generalized *Onchocerca volvulus* infection (126). This chronic helminthic infection, which causes “river blindness” late in life, has no recognized effects on reproductive fitness, while malaria (fatal in 1% of local children prior to their fifth birthday) has a major effect on reproductive fitness. The price of 10,000 years of selection for HLAs protective against malaria appears to be susceptibility to *Onchocerca* infection.

Several HLA class and loci associations have been repeatedly reported with specific bacterial and viral infections. Tuberculosis studies performed in multiple countries since 1989 have consistently found class II, in particular DRB1, associations with infectious outcomes (127). Class I associations have consistently been significant in HIV-1 outcomes (106).

In summary, the study of HLA–microbe interactions continues to be a complex task of studying two moving targets, i.e. the highly polymorphic human MHC region and continuously evolving microbial pathogens. Published studies have been limited by numerous variables, but a greater understanding of the complex relationship between HLA and infection is emerging. Despite reports of HLA antigens functioning as coreceptors for viral entry (128), most available evidence suggests that the variability in infectious disease outcomes associated with specific HLA alleles is due to qualitative differences in the microbial peptide presentation to the immune system. Unfavorable outcomes are generally attributed to inefficient peptide presentation; however, it has been suggested that overly efficient HLA peptide presentation may lead to an excessive inflammatory reaction and poor outcomes (129). The role of HLA in host susceptibility to infection continues to be defined, and although some reported associations may ultimately prove to be due to genes linked to the MHC other than HLA, two principles have emerged: (1) HLA and microbial

populations coevolve, and consequently (2) multiple alleles at specific loci appear to be linked to outcomes in different populations.

### 39.4.11 Interferon Gamma Receptor Genes (*IFNGR1* AND *IFNGR2*)

The interferon gamma receptor (IFN $\gamma$ R) is expressed in all nucleated cells as a tetramer composed of two IFN $\gamma$ R1 and two IFN $\gamma$ R2 subunits (130). *IFNGR1* maps to 6q23–24, and *IFNGR2* maps to 21q22.1–22.2. Mutations in both *IFNGR1* and *IFNGR2* have been reported, although *IFNGR1* mutations appear to be more common. The increased infectious disease risks associated in both cases appear to be *Salmonella* and mycobacterial infections. Three cases attributable to *IFNGR2* were associated with three different homozygous mutations. IFNGR1 deficiency can be divided into two groups: patients with homozygous mutations leading to a complete loss of expressed gene product and patients with a single mutant allele arising at a common mutational “hot spot” and resulting in inheritable risk for recurrent infections with a dominant inheritance pattern (i). In a study of 22 patients with autosomal recessive “complete” IFNGR1 deficiency and 38 patients with autosomal dominant “partial” deficiency, a genotype–phenotype correlation was made linking “complete” deficiency to more severe risk of morbidity and mortality (132).

### 39.4.12 Interleukin-12 Receptor, Beta-1 (*IL12RB1*)

The cell surface receptor for interleukin-12 (IL-12) is a heterodimer composed of beta 1 ( $\beta$ 1) and beta 2 ( $\beta$ 2) chains. The  $\beta$ 1 receptor is encoded at chromosome 19p13.1, and the  $\beta$ 2 gene is in 1p31.2. Coexpression of both functional subunits is required for IL-12 binding.

Homozygous mutations *IL12RB1* have been associated with *Salmonella* and *Mycobacterium* infections in seven published cases (133,134). Six different mutations were demonstrated in *IL12RB1* of six different patients (130). One child who died at eight years of age without sequence analysis was presumed homozygous for the same mutation as his brother. The six patients included in the sequence analysis had intermittent infections but were apparently free of other adverse consequences (135).

### 39.4.13 Toll-Like Receptor 2

Toll-like receptor 2 (TLR2) is one of at least nine different human Toll-like receptors (TLRs) that have been described, and their name is based on homology with the *Drosophila* toll protein (136). In general, TLRs appear to function as bacterial sensors. The gene locus for *TLR2* is at 4q32, and it encodes a 784 amino acid protein. Experimental data suggests that a highly polymorphic (GT)

dinucleotide repeat, which is 100 nucleotides upstream from the *TLR2* translational start site in intron 2, is associated with variable expression of *TLR2* in response to cytokine stimulation (137). The numbers of GT repeats found in participants of this study varied from 12 to 28, and there were significant differences in allele distribution between African-Americans and Caucasians ( $P=0.008$ ) and between African-Americans and Koreans ( $P=0.0003$ ). Functionally, *TLR2* genes with shorter or longer GT repeats had higher promoter activity than mid-sized GT repeats when stimulated with interferon-gamma (IFN- $\gamma$ ) (137).

Association studies have examined several *TLR2* polymorphisms in relation to infectious diseases. A promoter polymorphism in *TLR2* (T-16933A) was used to define two groups in a study of the prevalence of infection in critically ill adults, and the A/A genotype was significantly associated with both sepsis and Gram-positive infection (68). In a small study, a *TLR2* missense mutation was found in 9% of patients with staphylococcal sepsis (Arg 753Gln), compared to less than 3% of normal controls (138). While the association of this polymorphism with Staphylococcal infection was not supported in the study by Moore and colleagues (139), the importance of *TLR2* in protection against staphylococcal infection has been supported in a murine knockout model (140). Another human missense mutation, the Arg677Trp polymorphism (C2029T nucleotide substitution), has been associated with tuberculosis in Tunisian patients ( $P<0.0001$ ) (141) and leprosy in Korean patients (142). However, a recent report suggesting that C2029T may only be found in a pseudogene that lies 23 kb upstream from *TLR2* (143) has called the associations with this SNP into question, and further study will be required to discern whether or not it is indeed associated with altered risk of mycobacterial infection.

#### 39.4.14 Toll-Like Receptor 4 (TLR4)

The locus for *TLR4* is at 9q32–q33, and the gene product is known to exist in at least four isoforms of 639 to 839 amino acid length. Of the human TLRs, it appears that the data to support the notion that they function as “endotoxin sensors” is best developed in relation to *TLR4*. The Asp299Gly amino acid substitution in the extracellular domain of *TLR4* (created by the A896G polymorphism) is associated with a blunted response to inhaled bacterial LPS. In vitro experiments support the notion that it is the Asp299Gly substitution rather than another common substitution (i.e. C1196T, which results in Thr399Ile) that interrupts LPS-mediated *TLR4* signaling (144). Several studies have now found that the 896G and the 1196T polymorphisms are in fact linked in the majority of patients. The 896G allele was associated with both a diminished inflammatory response to gram-negative pathogens and a decreased risk of

atherosclerosis in a study of patients in Bruneck, Italy (145). In this study, the 55 subjects who had the 896G allele were shown to have lower levels of proinflammatory cytokines, more susceptibility to severe bacterial infections, a lower risk of carotid atherosclerosis, and a smaller intima-media thickness in the common carotid artery. In these patients, the 896G allele was heterozygous in 53 and homozygous in 2 of the subjects, and 896G cosegregated with 1196T in 46 of the 55 patients (145). In another study of the same *TLR4* A896G polymorphism in relationship to a *Legionella pneumophila* outbreak in The Netherlands, the 896G allele showed a protective association (146). While further study of these links are clearly needed, associations between the 896G allele and both “protection from” *L. pneumophila* as well as “susceptibility to” other Gram-negative bacteria are not inherently contradictory. Since *L. pneumophila* and other bacteria differ greatly in both their LPS and their pathogenesis, the optimal protective *TLR4* response could also vary significantly.

#### 39.4.15 Toll-Like Receptor 5 (TLR5)

The gene encoding *TLR5* is on chromosome 1 (1q41). A common SNP (C1174T) has been described in Caucasians with the allele frequency of approximately 10%. This cytosine–thymidine transition changes the arginine at amino acid 392 to a stop codon (*TLR5* 392X) and is predicted to prematurely truncate *TLR5* in the extracellular domain and cause the loss of the transmembrane domain and the entire signaling cytoplasmic tail (147). In a separate analysis of the same *L. pneumophila* outbreak discussed earlier, Hawn and colleagues concluded that *TLR5* 392X exerted a dominant effect and that heterozygous *TLR5* 392X individuals are more susceptible to *L. pneumophila* because of impaired production of proinflammatory cytokines (147).

### 39.5 INTRACELLULAR PROTEINS

#### 39.5.1 Cytokine-Inducible SH2-Containing Protein

The cytokine-inducible SH2-containing protein (CISH) has been linked to risk for several different infectious diseases, and its gene, *CISH*, is located in chromosome 3 (3p21.3). Its pivotal role in different infectious diseases is explained by its intracellular role in interleukin-2 (IL-2) signaling. A recent report suggests that variant *CISH* alleles that are associated with decreased *CISH* expression are associated with an increase in the overall risk of tuberculosis, malaria, and bacteremia (148). In a study of over 8000 individuals in Africa and Asia, these authors found that having one of the common variants associated with decreased *CISH* expression was associated with an 18% increased risk of one of these major infections (148).

### 39.5.2 Galactose-1-Phosphate Uridyltransferase (GALT)

The gene encoding galactose-1-phosphate uridyltransferase (*GALT*) is located in chromosome 9 (9p13). Galactosemia, caused primarily by *GALT* deficiency, is an autosomal recessive inborn error of metabolism that has been associated with greater than 100 different mutant genotypes (149). This metabolic disorder is discussed in detail in Chapter 93, but warrants mention here because of the association of neonatal Gram-negative sepsis with this disorder (150). Although a comprehensive understanding of the pathogenesis of this bacteremic state is not available, impaired neutrophil function in neonates attributed to increased galactose is likely to be a significant contributing factor (151).

### 39.5.3 Glucose-6-Phosphate Dehydrogenase (G6PD)

The gene encoding glucose-6-phosphate dehydrogenase (*G6PD*) is located in chromosome Xq28. This enzyme is believed to be essential to cellular function, and quantitative variations in enzyme function appear to be clinically significant in mature erythrocytes. The phenomenon of X-linked inactivation in females was uncovered in the study of *G6PD*-deficiency; this results in heterozygous females having two cellular populations: *G6PD*-deficient and *G6PD*-nondeficient cells (152). At least 95 different mutations have been associated with *G6PD* deficiency (149), and these sequence changes account for the observed range of enzyme activities (from mild to severe deficiency). The known mutations are almost entirely point mutations, although four small in-frame deletions (of three or six base pairs (bp)) have been reported. It appears that a mutation that would result in a completely nonfunctional enzyme would be lethal (153).

In the 1960s, when the increased population prevalence of *G6PD*-deficiency in malarious zones was noted, it was suggested that, like sickle-cell disease and thalassemia, *G6PD* deficiency likely offers a survival advantage in malaria. However, published data to support this hypothesis was minimal until 1995 when data suggesting that both female heterozygotes and male hemizygotes have a 46–58% reduced risk for severe malaria was reported (154). While many mechanisms of selective advantage have been proposed, data suggests that early phagocytosis of *P. falciparum*-infected erythrocytes occurs. Phagocytosis is induced by parasite-associated erythrocyte membrane damage more readily in *G6PD*-deficient cells (155).

A selective disadvantage of *G6PD* deficiency has been proposed to explain the lack of allelic fixation in sub-Saharan African populations (154). The disadvantage is not clear, but an increased incidence of bacterial sepsis in neonates may be a contributing factor (156).

### 39.5.4 Alpha-Globin (HBA1 and HBA2)

Four functional  $\alpha$ -globin (*HBA*) alleles are present per diploid erythroblast, with two tandem *HBA* alleles at each 16p13.3 locus; these genes, *HBA1* and *HBA2*, have identical coding sequences with some variation in the noncoding portion. The protein  $\alpha$ -globin combines with  $\beta$ -globin to form the functional  $\alpha_2\beta_2$  tetramer of adult hemoglobin. “Thalassemia” is used to describe inherited defects in globin synthesis;  $\alpha$ -thalassemia is secondary to *HBA* mutations (Chapter 71). Greater than 30 different  $\alpha$ -thalassemia-inducing mutations exist (149). Persons with  $\alpha$ -thalassemia trait have three functional alleles and an essentially normal hematologic phenotype, while persons with a mild hypochromic anemia generally have two functional copies.

Before the mid-1980s, it was difficult to dissect the interactions of  $\alpha$ -thalassemia and infection from the effects of the  $\beta$ -hemoglobinopathies. Flint and colleagues studied human populations in the Southwest Pacific nations of Papua New Guinea and Melanesia, who have  $\alpha$ -thalassemia and no  $\beta$ -thalassemia or sickle-cell disease. This study suggested that the level of malaria endemicity correlated with the gene frequency of  $\alpha$ -thalassemia and argued that a selective pressure was being exerted by malaria in favor of  $\alpha$ -thalassemia (157). Further study has now demonstrated that the  $\alpha$ -thalassemia trait is associated with a reduced risk of severe malaria (0.66) with an even greater reduced risk associated with  $\alpha$ -thalassemia itself (0.40) (158). There was also a reduced risk for other serious infections associated with  $\alpha$ -thalassemia and trait in this study, although the reason for this association is not apparent (158).

### 39.5.5 Beta-Globin (HBB)

Two functional alleles encode wild-type  $\beta$ -globin, one at each 11p15 locus. This difference in gene copy number distinguishes the hemoglobinopathies associated with *HBB* from the  $\alpha$ -hemoglobinopathies that stem from mutations in any of the four functional *HBA* alleles. In addition to  $\beta$ -thalassemias associated with defects in  $\beta$ -globin synthesis, there are important structural  $\beta$ -hemoglobinopathies (159).

Sickle hemoglobin (HgbS) is encoded by a *HBB* allele with a point mutation in the sixth codon. In a series of scientific discoveries spanning from 1949 to 1977, this structural hemoglobinopathy was first described as “a molecular disease” based on hemoglobin electrophoresis differences (160), then as a single amino acid substitution linked disease (161), and finally as an SNP-linked disease (162). The A to T change that codes for a glutamic acid to valine substitution constituted the first host microbial resistance trait and the first human disease linked to a SNP.

In countries with endemic malaria, HgbS demonstrates the principle of balanced polymorphism since the

heterozygous state (i.e. sickle-cell trait) is associated with a reduced risk of severe malaria. Either homozygous state confers a disadvantage: HgbS/HgbS causing sickle-cell anemia and  $\beta$ Hgb/ $\beta$ Hgb risking severe morbidity or even mortality due to malaria. Heterozygous advantage may be responsible for the success of the five different HgbS alleles occurring as separate mutational events in five different human populations (163,164). In addition to its multiple clinical manifestations, sickle-cell anemia is associated with an increased susceptibility to a number of infectious complications including parvovirus-induced aplastic crisis and bacterial infections with encapsulated bacterial pathogens such as *Streptococcus*, *Haemophilus*, and *Salmonella* organisms (165).

Unlike HgbS,  $\beta$ -thalassemia is associated with a variety of genetic alterations including SNPs, substitutions, deletions, insertions, and rearrangements. The shared features of these various mutations are quantitative defects in  $\beta$ Hgb synthesis. The heterogeneous group of mutations that lead to  $\beta$ -thalassemia occurs in a manner that suggests that  $\beta$ -thalassemia affords protection against malaria (166).

### 39.5.6 Parkinson Disease (Autosomal Recessive, Juvenile) 2, Parkin (*PARK2*), and *PARK2* Coregulated (*PACRG*)

A bidirectional promoter at chromosome 6q26 is shared by *PARK2* and *PACRG*. The gene products of both of these genes are involved in intercellular ubiquitin-mediated proteolysis. The first disease association at this locus was juvenile-onset Parkinson disease, and there are now multiple different alleles of *PARK2* associated with this form of autosomal recessive Parkinson disease (i.e. onset at less than 20 years of age). In a Vietnamese cohort, Mira and colleagues (2004) found significant associations between leprosy and polymorphisms in the 5' regulatory region shared by *PARK2* and *PACRG*. They went on to confirm an association between this regulatory region and leprosy in a Brazilian cohort. Using reverse transcription polymerase chain reaction (RT-PCR) analysis they detected expression of *PARK2*, and to a lesser extent *PACRG*, in the primary target cells of the causative agent of leprosy (i.e. *Mycobacterium leprae*) (167).

### 39.5.7 Solute Carrier Family 11, Member 1 (*SLC11A1*)

*SLC11A1* was formerly known as natural resistance associated macrophage protein 1 (NRAMP). NRAMP 1 is a human macrophage membrane protein that is recruited to the phagosomal membrane after phagocytosis and apparently acts as a divalent cation transporter (168). The human gene and its protein product were sought following identification of the murine homolog in which a point mutation was associated with increased

susceptibility to intracellular parasites (169). *NRAMP1* is located in chromosome 2q35 (170) and is expressed exclusively in immune phagocytes (171).

Eleven *NRAMP1* polymorphisms have been identified (172), including four mutations that have been associated with increased susceptibility to active tuberculosis (172–174). Data suggests that NRAMP 1 plays a role in the development of lepromatous leprosy (175) and HIV-1 infection (176), as well as idiopathic conditions such as sarcoidosis (177) and autoimmune diseases (178). A recent study examined the association of four intragenic polymorphisms (274C/T, 469+14G/C, D543N, and 1729+55del4) with tuberculosis in a pediatric population (179). This group found the 274C polymorphism to be most significantly associated with rapid progression from infection to clinical disease.

### 39.5.8 Vitamin D Receptor (VDR)

The vitamin D receptor (VDR) is an intracellular protein, which is believed to act as a transcriptional regulatory factor (180). This receptor binds to 1,25-dihydroxyvitamin D3. VDR maps to 12q12–q14 and contains a total of 11 exons including eight protein coding exons. Along with their role in calcium metabolism, vitamin D and VDR are also involved in the immunoregulatory functions of monocytes and activated lymphocytes.

The VDR allele containing a T to C substitution at codon 352 may confer susceptibility to several important infectious diseases. Although this “silent” polymorphism does not alter the protein’s amino acid sequence, it is associated with increased mRNA quantities (181). Mutant alleles containing the C substitution are labeled as “t” genotype, while “T” genotype represents the wild-type allele. Homozygotes for “t” (i.e. tt) appear to have a decreased risk for chronic hepatitis B and decreased active tuberculosis (182,183). Heterozygotes for Tt appear less likely to develop leprosy (184). Whether this SNP is causally related or simply linked to the causative mutation is not yet fully elucidated (181).

## 39.6 EXTRACELLULAR PROTEINS

### 39.6.1 Chemokine, CC Motif, Ligand 3-Like 1 (*CCL3L1* and *CCL3L3*)

Segmental duplication within chromosome 17q21.1 has led to the inclusion of two copies of *CCL3L1* in the reference sequence of the human genome; *CCL3L3* is used to designate the centromeric copy (185). *CCL3L1* is among a group of chemokine receptor ligands that were formally designated as macrophage inflammatory proteins (MIP1 $\alpha$  and MIP1 $\beta$ ), and the gene product of *CCL3L1* has been shown to bind to several chemokine receptors including chemokine binding protein 2 (CCBP2) and chemokine (C-C motif) receptor 5 (CCR5). The gene copy numbers within individuals can

vary between zero and six, although it appears that only rare individuals have either zero copies or more than four copies (186).

The endogenous ligands of CCR5, namely, CCL3L1, as well as CCL3 and CCL5, can block the entry of HIV-1 into cells. This blockade is a consequence of inhibiting CCR5's coreceptor function for macrophage-tropic strains of HIV-1 (50) and (51). The increased affinity of CCL3L1 binding to CCR5, when compared to other CCR5 ligands such as CCL5 or CCL3, suggested that it might have a central *in vivo* role in inhibiting HIV-1 replication (187). The notion that CCL3L1 has a significant functional role in blocking HIV-1 pathogenesis is supported by the demonstration that the possession of a *CCL3L1* copy number lower than the population average is associated with a markedly enhanced risk for HIV-1-associated disease progression (188).

### 39.6.2 Chemokine, C-C Motif, Ligand 5 (CCL5)

CCL5 acts as a ligand for the receptor CCR5 and has previously been referred to as RANTES and SCYA5 in the literature. The gene locus is found at 17q11.2–q12, and the 91 amino acid gene product, which is secreted by CD8 T-cells, acts as a chemoattractant for monocytes and CD4 T-cells (189).

The binding of CCL5 to CCR5 competitively inhibits HIV-1 binding and entry into cells. There have been two noncoding polymorphisms identified associated with variable CCL5 expressions and thereby associated with altered clinical course of HIV-1 infection. The CCL5 promoter polymorphism -28G in a study of Japanese patients, while not associated with incidence of infection, was associated with increased gene expression in infected individuals and delayed HIV-1 disease progression (190). An intronic polymorphism "In1.1T/C" (T168923C) is associated with diminished gene product and accelerated progression to AIDS; in one study 168923C was present in 36% of African-Americans (191). In addition to its observed role in HIV progression, there are data emerging to suggest that 16923C is also associated with diminished response to antiviral therapy for chronic HCV infection (192).

### 39.6.3 Chemokine, CXC Motif, Ligand 12 (CXCL12)

The gene for CXCL12, formerly known as stromal-cell-derived growth factor 1 (SDF1), is found at 10q11.1. This gene yields two isoforms by alternate splicing (193): CXCL12 transcript variant 1 is associated with a 3560 bp mRNA derived from four exons, and CXCL12 transcript variant 2 is associated with a 1940 bp mRNA derived from three exons. CXCL12 binds to CXCR4 on the surface of lymphocytes and downregulates CXCR4 expression by inducing endocytosis (194,195).

A polymorphic variation in the 3'-UTR of transcript variant 2 (or SDF1-beta) has been associated with altered HIV-1 progression. "SDF1-3'A" was used by the authors to designate the allele with a G-to-A transition at position 801 (counting from the ATG start codon) in the 3' UTR. HIV-1 infected persons who were homozygous for 801A (SDF1-3'A/3'A) showed a delay in the onset of AIDS (196).

### 39.6.4 Chitinase 1 (CHIT1)

The human chitinase gene (*CHIT1*) has been assigned to chromosome 1q31–q32, and its gene product is a circulating enzyme also known as plasma chitotriosidase or methylumbelliferyl tetra-*N*-acetylchitotetraoside hydrolase. This enzyme is excreted by macrophages and is believed to play a role in degrading chitin, which is a cellulose-like structural polysaccharide that is generated by numerous microorganisms. Although the pathophysiological implications are unclear, the median activity of chitotriosidase in patients with Gaucher disease was more than 600 times the median value in plasma of healthy volunteers, and during enzyme supplementation therapy of Gaucher disease chitotriosidase activity declined dramatically (197).

A polymorphism consisting of a 24 bp duplication in exon 10, resulting in the activation of a cryptic 3' splice site and an in-frame deletion of 87 nucleotides has been described (198). This polymorphism leads to diminished chitinase activity in heterozygotes and an absence of chitinase activity in homozygotes (198). This polymorphism exists in diverse populations, with a reported allele frequency of 40% in South Asia, 20–25% in Europe, and 0–2% in Africa (198–201). A study in southern India found an association between chronic filariae infection with *Wuchereria bancrofti* and homozygosity for the allele carrying the 24 bp duplication (199).

### 39.6.5 Interleukin-1, Beta (IL-1B) and Interleukin-1 Receptor Antagonist (IL1RN)

Interleukin-1 activity, defined as its capacity to induce IL-2 synthesis in T-lymphocyte cell lines, was attributed to two distinct genes, which lie adjacent to each other on chromosome 2: *IL1A* and *IL1B* (202). *IL1B*, along with eight other interleukin-1 family genes, forms a cytokine gene cluster at 2q14. Proteolytic cleavage by CASP1 is required to convert the IL-1B protein precursor to functional IL-1 $\beta$  (203). Evidence suggests that some microbial pathogens (such as *Streptococcus pyogenes*) may directly alter production of active IL-1 $\beta$  through the expression of a bacterial cysteine protease that cleaves the human IL-1B precursor to yield active IL-1 $\beta$  (204). IL-1 $\beta$  helps drive T-helper lymphocyte 1 (Th1) responses and stimulate the synthesis of T cell proliferative cytokines such as IL-2 (205).

The interleukin-1 receptor antagonist gene (*IL1RN*) is located within the same cytokine gene cluster at 2q14 as *IL1B*. The *IL1RN* protein competitively inhibits IL-1A and IL-1B binding to the IL1R. As such, when *IL1RN* was described in 1990, it was the first specific cytokine receptor antagonist identified (206). *IL1RN*\*2 has been used to designate the polymorphic variant with two 86bp tandem repeats (VNTR) in intron 2 of *IL1RN* (207).

Wilkinson and colleagues studied potential associations between *IL1B* and *IL1RN* polymorphisms and clinical tuberculosis in a group of London patients who were of Indian origin (208). They concluded that *IL1RN*\*2 was associated with elevated *IL1RN* production and a reduced Mantoux response to purified protein derivative of *M. tuberculosis*. On the other hand, a non-*IL1RN*\*2 haplotype was associated with increased IL-1B production and linked to pleural tuberculosis.

An *IL1B* promoter polymorphism (C-31T) has been linked to expression of the gene; the T allele is associated with increased IL-1 $\beta$  concentrations and is therefore considered “proinflammatory.” *IL1B*-31T has been associated with hypochlorhydria induced by gastric infection with *H. pylori* and the associated development of gastric carcinoma (209). In this study, carriers of *IL1B*-31T had an autosomal dominant increased gastric cancer risk at an odds ratio of 1.9 (95% CI, 1.5–2.6).

### 39.6.6 Interleukin-4 (IL-4)

The IL-4 gene is adjacent to the IL-13 gene on chromosome 5q31.1, and these genes together with *IL5* and others form a cytokine cluster in the chromosome region. A long-range regulatory element, spread over 120kb, is believed to coordinate the expression of *IL4*, *IL5*, and *IL13* (210). IL-4 is a pleiotropic cytokine that regulates Th2 lymphocyte subset development and IgE production (205,211). IL-4 downregulates CCR5 expression and upregulates the expression of CXCR4 (212). A promoter polymorphism (C-589T) has been correlated with altered promoter activity, and the -589T allele, which is associated with increased activity, was found to have an allele frequency of 0.15 in a French population and 0.64 in a Japanese population (212).

HIV-1 viral load was lower in patients with IL-4 -589T and was associated with delayed progression to AIDS and death. These results are consistent with a protective effect due to a reduction in HIV replication, and it is in agreement with in vitro experiments that showed that IL-4 downregulates CCR5 expression and inhibits replication of R5 HIV-1 strains (212). Interestingly, IL-4 -589T enhances acquisition of X4 HIV-1 strains, and in the homozygous state this IL-4 polymorphism may negatively impact late-stage prognosis (213).

Choi and colleagues attempted to correlate the development of chronic disseminated candidiasis in patients

with acute leukemia with a more detailed polymorphic analysis of the IL-4 promoter. They defined three polymorphic haplotypes at positions -1098, -589, and -33; those haplotypes are TTT, TCC, and GCC (214). They associate greater risk for chronic disseminated candidiasis, a form of fungal infection observed primarily in patients with acute leukemia, with TCC, and apparent protection from CDC with TTT (214).

### 39.6.7 Interleukin-10 (IL-10)

The human IL-10 gene maps to chromosome 1q31–1q32 and multiple cytokine response elements are located in its 5' regulatory region including target sites for TNF, IFN- $\gamma$ , and IL-6 (215). Viral pathogens such as EBV (216) and the LPS of gram-negative bacteria (217) induce expression of human IL-10 from mononuclear cells. Elevated levels of serum IL-10 have been observed in patients with chronic HCV (218,219) and EBV (216) infections. Overall, much of the available data is consistent with a model in which diminished levels of IL-10 increase the risk for some autoimmune disease.

*IL10* promoter polymorphisms at positions -1082, -819, and -592 have been identified, and the GCC, ACC, and ATA haplotypes are linked, respectively, with high, intermediate, and low in vitro IL-10 production (220). The GCC haplotype as well as high in vitro IL-10 levels were associated with poor treatment response to interferon- $\alpha$  (IFN- $\alpha$ ) in patients with chronic HCV infection (221). Two studies of *IL10* promoter polymorphism and EBV were reported by Helminen and colleagues in a Finnish population; in this population the IL-10 ATA haplotype was associated with protection against primary EBV infection as well as increased in vivo IL-10 levels, and another report by this group associated the GCC haplotype with EBV seronegativity and ACC haplotype with severe EBV infection (222,223). The basis for the differences in the observed in vitro versus in vivo IL-10 production associated with the haplotypes has not been elucidated. Shin and colleagues (224) reported an increased susceptibility to HIV-1 infection and more rapid progression to AIDS in patients with a C-to-A polymorphism at position -592 of the *IL10* promoter. This -592A association appeared to be autosomal dominant in its effect.

### 39.6.8 Interleukin-28B (IL-28B)

The gene for interleukin-28B (*IL28B*) is found along with *IL28A* and *IL29* in a cytokine cluster at 19q13.13 and codes for IFN $\lambda$ 3 (225). This gene is associated with the spontaneous clearance of HCV infection and with the response to standard therapy with IFN- $\alpha$  and ribavirin treatment in individuals with chronic HCV infection (226–229). The fine mapping of the pathogenic variant is being pursued (230). The upstream haplotype associated with viral clearance at SNPs rs12979860 and

rs8099917 is CT, and the persistence haplotype at these SNPs is TG (225).

### 39.6.9 Mannose Binding Lectin 2 (MBL2)

*MLB2* at chromosome 10q11.2 encodes a serum protein that is secreted by hepatocytes and facilitates the opsonization and phagocytosis of extracellular microbial pathogens (231).

In 1991, Sumiya and colleagues linked recurrent infection, low serum concentration of this protein, and an amino acid change at codon 54 (G54D). Since that time, a body of literature has evolved that examines the relationship between serum MBL2 protein levels and six polymorphisms (three coding SNPs, one 5' UTR SNP, and two promoter SNPs). Within various populations studied, the coding SNPs are in linkage disequilibrium with the noncoding SNPs (232). Each of the three coding SNPs is associated with lower serum MBL2 protein levels, and each disrupts the tandem motif repeat (Gly-X-Y) in the collagenous region of the protein; the variants are frequently referred to as allele A (wild-type), allele B (G226A and gly54asp), allele C (G235A and gly57glu), and allele D (C219T and arg52cys) based on the chronological order in which they were identified (233–235). The three variants have a combined allele frequency of 20% in Caucasians, and the serum protein concentrations are diminished in heterozygotes and essentially undetectable in individuals with either homozygosity for a variant allele or compound heterozygosity for variant alleles (236). Along with infectious disease associations, the genotypes causing low levels of MBL2 have also been associated with autoimmune diseases; for example, there are studies linking low-concentration genotypes with erosive rheumatoid arthritis in both Chinese and Caucasian patient groups (237,238).

The most striking infectious disease association with *MBL2* to date is the association of the genotypes that cause low MBL2 protein concentration and invasive meningococcal infections (239). The “low concentration” variant alleles have been strongly associated with invasive pneumococcal infection, as well as febrile neutropenia and infection in the setting of chemotherapy and hematopoietic stem cell transplant (240). The clinical course and response to therapy of numerous other infections have been associated with low-concentration alleles, including mycobacterial infection, HIV-1, hepatitis B and C viruses, and aspergillosis (240).

The high frequencies of these variant alleles in many populations has led to the suggestion that MBL structural variants could represent a case of balanced polymorphisms. One theory suggests that heterozygosity for MBL variant proteins may confer protection against intracellular parasites that use opsonization via complement as a route of gaining cellular entrance, and another theory suggests that the MBL-mediated route of

complement activation may, in some circumstances, be detrimental for the host (232).

### 39.6.10 Surfactant, Pulmonary-Associated Protein B

Surfactant, Pulmonary-Associated Protein B (*SFTPB*) (2p12–p11.2) encodes a highly hydrophobic protein component of pulmonary surfactant. The surfactant lowers surface tension in the alveoli of the lung, and an autosomal recessive condition known as “congenital alveolar proteinosis” is associated with a deficiency of pulmonary surfactant protein B (241). A polymorphism in the *SFTPB* coding sequence (T1580C) leads to an amino acid substitution that results in the loss of a N-glycosylation site. In a study of 402 patients with community-acquired pneumonia, comparing the 1580C and the 1580T alleles, patients with C/C were at a significantly higher risk of respiratory failure compared to those with T/C and T/T (242).

### 39.6.11 Transforming Growth Factor Beta-1

Transforming growth factor  $\beta$ -1 (*TGFB1*) is encoded at 19q13.1; *TGFB1* shares significant sequence identity with *TGFB2* and *TGFB3* (243). A polymorphism at position +915 (codon 25) resulting in the homozygous arginine/arginine genotype has been associated with high levels of TGF  $\beta$ -1 production in stimulated lymphocytes (244). HCV-associated hepatic fibrosis (245) has been linked with the arginine/arginine sequence genotype.

### 39.6.12 Tumor Necrosis Factor (TNF) and Lymphotoxin A (LTA)

TNF is a proinflammatory cytokine mainly secreted by cells of monocyte lineage (246). The TNF (formerly known as  $\text{TNF}\alpha$ ) and the LTA (formerly known as  $\text{TNF}\beta$ ) genes are separated by only 1.2 kb at chromosome 6p21.3. These genes lie in the class III region of the human MHC complex of chromosome 6, approximately 250 kb centromeric of the HLA-B locus and 850 kb telomeric of *HLA-DR*. It may actually be polymorphisms within these genes that contribute to some of the associations that have been made with MHC alleles with specific autoimmune and infectious diseases. The recent introduction of therapeutic agents that block TNF signaling has led to an association between pharmacological TNF blockade and tuberculosis reactivation and thereby reinforced the notion that effective TNF signaling is necessary for control of infection (247).

*TNF* promoter polymorphisms have been associated with altered expression of TNF. Association studies, which have used the *TNF* promoter polymorphism G-308A to examine an extended MHC haplotype, often use the designations *TNF1* (for -308G)

and *TNF2* (for -308A). The A substitution at position -308 ("TNF2") results in a much stronger transcriptional activator and increased levels of TNF expression (248). This -308A allele is associated with worse outcomes in cerebral malaria (249) and leishmaniasis (250). Presumably, increased levels of TNF may contribute to disease severity and morbidity in systemic infections. Increased levels of plasma TNF were present in Gambian children with cerebral malaria, and the highest TNF levels were noted in fatal cases (251). Gambian children homozygous for the -308A allele were at significantly increased risk for death or severe neurologic sequelae due to cerebral malaria (249). The *TNF* -308A allele has also been associated with the development of HIV-1 dementia (252), Guillain-Barre syndrome following campylobacter infection (253), and lepromatous leprosy (254).

Cerebral malaria has also been associated with the *TNF* -376GA allele (255). In another study, severe malarial anemia was shown to be significantly associated with *TNF* -238A after stratification for the HLA

haplotype (256). Polymorphisms in both TNF and LTA are related to the development of ulcer disease in patients with *H. pylori* (257).

### 39.7 CONCLUSION

There is a growing list of human mutations and polymorphisms that are associated with variable susceptibilities to infection. For the most part, the polymorphism associations have been made in cases where both the infectious disease and the genetic variants are common, and a picture of host defenses extending beyond the classical immune system is emerging in conjunction with these findings. The susceptibility phenotypes fall into classic Mendelian inheritance patterns in many cases (Table 39-2). In addition to the examples of altered susceptibility to infections reviewed in this chapter, there is a growing database of information regarding variable responses to antibiotics and other therapeutic interventions in infection. As a host genetic basis of clinical infectious disease management, which includes both

**TABLE 39-2 Non-HLA Microbe–Gene Susceptibility Associations**

Microbe	Gene/Gene Product	Associated Susceptibility
HIV-1	FUT 2 CCR5 CCR2 CX <sub>3</sub> CR1 NRAMP1 SDF1-3'A	Heterosexually acquired infection Infection and progression to AIDS Progression to AIDS Progression to AIDS Progression to AIDS Progression to AIDS
Parvovirus B19	PK synthase	Infection
Hepatitis B virus	VDR	Persistent infection
Hepatitis C virus	IL-28B	Persistent infection Treatment response
<i>Haemophilus influenzae</i>	FUT 2	Invasive infection
<i>Streptococcus pneumoniae</i>	FUT 2	Invasive infection
<i>Neisseria meningitidis</i>	FUT 2	Invasive infection
<i>Pseudomonas aeruginosa</i>	CFTR	Pulmonary infection
<i>Salmonella</i> spp.	CFTR IFNGR	Gastrointestinal infection Systemic infection

### Biography

**Michael F Murray, MD**, a former primary care provider, is now the clinical chief of genetics at Brigham and Women's Hospital in Boston. He trained in internal medicine at the Cleveland Clinic and then went on to do fellowships in Infectious Diseases and Medical Genetics. Dr Murray directs the annual course in "The Genetic Basis of Adult Medicine: What the Primary Care Provider Needs to Know" and is the program director for a combined training program in Internal Medicine and Medical Genetics. He leads the Adult Genetics Clinic at Brigham and Women's Hospital where over 300 patients per year are evaluated, diagnosed, and managed. His research interests include the integration of electronic family health history tools into medical practice and the use of whole genome testing in medicine.

### 40.1 INTRODUCTION

The idea of replacing a diseased or damaged part of the body of an individual—the recipient—with the same part provided by another healthy individual—the donor—has always been present in the human mind. Greek mythology is full of examples of chimeras—imaginary animals composed of parts coming from individuals of different species. If, on one hand, chimeras can represent an artistic version of a successful xenotransplantation intervention (i.e. a transplant between individuals of different species), on the other hand, picturesque examples of dreamed allotransplantation (i.e. a transplant between two genetically different individuals of the same species) are also available (1).

The most elegant representation of this mental concept is perhaps the famous painting of Fra Angelico (1387–1455), an altarpiece in the San Marco Church in Florence, Italy (Figure 40-1). The painter here represented the miracle performed by Saints Cosmas and Damian in Constantinople as narrated in a third-century legend. According to the legend, these twin brothers, one is a physician and the other a surgeon, replaced the cancerous leg of a white church sacristan with a healthy limb from a recently deceased Moor. The story is told that the sacristan walked around for the rest of his life with one white leg and one black leg (1–3).

There is, however, evidence that transplantation surgery was successfully performed more than 2000 years ago by ancient Hindu vaidya (1,4). The reported

**FIGURE 40-1** The healing of Justinian by Saint Cosmas and Saint Damian as portrayed by Fra Angelico in his painting conserved in the Museo di San Marco, Florence, Italy.

clinical interventions that involved the reconstruction of the nose using pedicle flap grafts from the patient's own forehead were similar in approach to the one described by the historian Calinzio who, in 1503, wrote in praise of the surgeon Branca who reconstructed the nose of a gentleman using skin removed from his slave (5). Calinzio added that: "for a time the new nose functioned well," then "suddenly grew cold," "turned blue," and "eventually fell off." Because the slave died on the same day, the slave's demise was blamed for the loss of the engrafted nose. Today, we know that the difference between these successful and unsuccessful transplants is that the first was an autologous transplant, and the other, an allotransplant. Branca's patient actually suffered a typical graft rejection, whereas the physician Gaspare Tagliacozzi was instead successful when, 100 years later (the year 1597), he tried to reproduce the vaidya's results by performing similar reconstructive rhinoplasty using skin flaps collected from the patient's arm (1,3).

We had to wait until the beginning of the twentieth century to find evidence of a fresh new look to the transplantation problem. It was, in fact, in 1912 when George Schöne clearly summarized conclusions that he gathered from different transplant attempts mostly performed in animals. The "laws of transplantation" were so defined: (1) autografts generally succeed; (2) allografts usually fail; and (3) xenografts invariably fail. "Blood relationship" was proposed as the biological barrier that separates donor from recipient: The closer the relationship, the more likely the graft will be accepted (1,3).

Twenty-five years later, Peter Gorer, an expert on tumor resistance in mice, defined the scientific basis

of this postulated blood relationship (6). Gorer was interested in explaining why tumors that could often be transplanted from one mouse to another failed to grow when transplanted in another strain of recipient mice. To determine what was different between the acceptor versus the rejecting strains, Gorer performed tumor transplants in  $F_1$ ,  $F_2$ , and backcross progeny of the three inbred strains of mice. The permissive trait was attributed to two independent genetic loci. On the basis of his knowledge of the blood groups, Gorer also attempted to distinguish the tumor-susceptible from the tumor-resistant animals on the basis of mouse erythrocyte agglutination driven by human serum. The successful experiments also proved that, similar to that for the ABO system, agglutination behaved as a simple Mendelian-dominant trait. Furthermore, rabbit anti-mouse erythrocyte sera were sufficient to define three mouse red blood cell antigens. The detection in the serum of the mice of anti-type-II-antigen antibodies coincided with rejection propensity (7). It was on this basis that Gorer joined forces with George Snell at the Jackson Laboratory in Bar Harbor, Maine, where they expanded the studies to Snell's "congenic" inbred mouse strains (8). Congenic strains are genetically identical except at a single chromosomal locus. Using congenic strains of mice, Gorer and Snell were able to determine that engrafted tumors were most likely able to "take" when the recipient mouse was of the same strain as the donor (9). More importantly, they also realized that survival of donor tissue was not limited to tumors but applied to any graft including skin. In addition, donor-specific antibodies first noted by Gorer in the graft-rejecting recipient were induced

not only by tumor grafting but also by any other tissue graft or blood transfusion (reviewed in Ref. (2)). By appropriate genetic crosses and backcrosses among their congenic inbred strains, Snell and Gorer identified a number of genetically independent loci controlling these immune responses, which they designated H for histocompatibility (i.e. compatibility between different tissues), followed by an arabic numeral in the order of discovery. The locus designated H-2 appeared to be more immunogenic than the others and corresponded to Gorer's original type-II antigen. This locus became known with time as the murine major histocompatibility gene complex (MHC). The MHC can be considered the molecular embodiment of Schöne's "blood relationship" (1).

Sir Peter Medawar tried to apply these concepts to help soldiers burned during World War II with skin grafts (10,11). He also came to the conclusion that, while autografts succeed, allografts actually fail after an initial period of survival. A second allograft from the same donor did not experience the latent period of the first; rather, it rejected in an accelerated manner. The survival of a second graft from a different donor was instead similar to that of the original graft, rejecting only after a latent period. Because the accelerated rejection could also be induced by injection into the recipient of donor leukocytes before engraftment, he hypothesized that "destruction of the foreign epidermis was brought about by a mechanism of active immunization." Specific antigens analogous to those of the ABO blood groups were supposed to be shared by skin and leukocytes and were responsible for the rejection response. Medawar's conclusions constituted the theoretical basis to postulate that immunosuppression might overcome the laws of transplantation.

In 1954, the first successful kidney transplant was performed between monozygotic twins, for which immunosuppression was not necessary (12). In 1959, the same team used an efficient immunosuppressive regimen to perform the first kidney graft between unrelated individuals (13). The graft survived for 20 years.

The observations that antibodies against transplantation antigens could be generated as the result of an immune response against transfused blood components suggested the possibility of identifying human histocompatibility antigens by serologic methods. In 1958, Jean Dausset produced the first human histocompatibility antiserum by deliberate immunization of one blood donor with leukocytes from another (14). This antiserum agglutinated the white blood cells of about 60% of his French donor panel. Concurrently, Payne and Rolfs showed that the sera of multiparous women often contained leukoagglutinins (15). This important finding promised readily available sources of reagent antisera with which to characterize human leukocyte antigens (HLA).

## 40.2 THE PHYSIOLOGIC FUNCTION OF MHC MOLECULES

The interpretation of the genetics of histocompatibility initially was, as presented, based on experiments, in which the histocompatibility antigens were only seen as the factors limiting tissue transplantation by promoting graft rejection. Later on, Pamela Bjorkman et al. discerned the physiologic function of the MHC molecules when they solved the X-ray crystallography structure of HLA-A2 and recognized the presence of a heterogenic population of bound peptides to what is now referred to as *Bjorkman's groove* (16,17).

Although with different efficiency, macrophages, monocytes, dendritic cells, and mature B-cells are all able to phagocytose foreign molecules, thus capturing "nonself" proteins invading our body and enzymatically cleaving them into smaller segments called peptides. This function is called "processing" of the antigenic protein. The peptides generated as the result of antigen processing are then protected from further cleavage and brought to the cell surface by MHC molecules able to accommodate the peptides in their antigen-combining site (18). The function of this site, the so-called peptide-binding groove discovered by Bjorkman et al. (reviewed by Bjorkman in Ref. (19)), was clearly determined once the interpretation of the crystal structure of the HLA molecule was completed (17). The HLA and peptide complex is then exposed at the cell surface (i.e. "presented") to a T lymphocyte that recognizes and engages it by its T-cell receptor (TCR) molecule. The antigen-presenting cell (APC) in this way activates T lymphocytes, causing them to divide and secrete specific factors (20). The signal from the engaged TCR to the inside of the cell is transmitted by a chain of molecules, the CD3 complex consisting of a series of dimers such as the CD3  $\delta\epsilon$ ,  $\gamma\epsilon$ , and  $\zeta\epsilon$  chains, that ultimately activate the enzymes necessary to stimulate cell division, cytokine receptor upregulation, and cytokine production (20,21) (Figure 40-2). Cytokines are secreted cellular hormones that can inhibit or stimulate other cells to become activated.

T-cells producing "helper" factors are known as T-helper cells (Th). On the basis of preferential secretion of certain cytokines, Th cells are conventionally divided into Th<sub>1</sub>, Th<sub>2</sub>, and Th<sub>17</sub> subgroups (22). Th<sub>1</sub> cells, which preferentially secrete interleukin 2, interferon- $\gamma$ , and tumor necrosis factor (TNF)- $\alpha$ , help other T cells, already committed to the cytotoxic T-cell lineage, to proliferate. These cytotoxic T lymphocytes (CTLs) destroy cells in our bodies that are infected or altered by the same foreign antigen to which the Th initially reacted. Th<sub>2</sub> cells primarily promote activation of B lymphocytes and subsequent antibody production via secretion of interleukins 4, 5, 6, 10, and 13 (22). Th<sub>17</sub> cells secrete interleukins 17A, 17F, 21, 22, and 26, and acting primarily at mucosal sites contribute to immune-mediated protection against bacteria and fungi (22).

T-helper cells can be recognized and distinguished from CTL cells by differences in coreceptor expression and MHC restriction. For example, CD4 and CD8 are T-cell coreceptor molecules that stabilize the TCR/antigenic peptide/MHC molecule complex while recognition is taking place (Figure 40-2). In general, CD4<sup>+</sup> T-cells preferentially recognize MHC class II molecules (see later) that have bound peptides derived from internalized, exogenous proteins and give rise to T-helper cell lineages, whereas CD8<sup>+</sup> T-cells react with MHC class I molecules (see later) complexed with cell-derived endogenous peptides and are activated to generate CTLs.

**FIGURE 40-2** The HLA class II molecule, expressed at the surface of an APC, interacts with the processed antigenic peptide, lodged in the Bjorkman groove of the molecule. The helper T cell recognizes the complex HLA molecule/antigenic peptide with its  $\alpha/\beta$  TCR. The accessory molecule CD4 stabilizes the binding of the TCR with the HLA molecule. CD4 provides antigen-mediated specific T-cell activation functions. The CD3 complex, composed of gamma ( $\gamma$ ), delta ( $\delta$ ), epsilon ( $\epsilon$ ), and zeta ( $\zeta$ ) molecules, transfers the signal of the successfully engaged TCR into the cytoplasm of the T cell. (From Conrad, B.; Trucco, M. *Superantigens as Etiopathogenetic Factors in the Development of Insulin Dependent Diabetes Mellitus*. Diabetes Metab. Rev. 1994, 10, 309–338.)

### 40.3 THE STRUCTURE OF HUMAN HISTOCOMPATIBILITY MOLECULES

HLA molecules are grouped into two classes based on their structure, function, and cellular expression. Class I (HLA-A, -B, and -C molecules) are characterized by a heavy (43 kDa)  $\alpha$  chain with three domains ( $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$ ) (Figure 40-3) that dimerizes with the  $\beta_2$  microglobulin, a short (12 kDa) protein, which provides the fourth domain necessary to stabilize the HLA molecule (23). Class I molecules are coexpressed on nearly all nucleated cells and platelets and are anchored via the transmembrane portion and the short cytoplasmic tail of the  $\alpha$ -chain only. Class II molecules (HLA-DR, -DQ, and -DP) consist of  $\alpha$  (34 kDa) and  $\beta$  (29 kDa) chains, each with two domains. Class II molecules are anchored by both chains, each of which can communicate across the membrane with cytoplasmic structures (Figure 40-3). These molecules are expressed primarily on B lymphocytes, macrophages, dendritic cells, activated T cells, and endothelial cells.

The two outermost domains of each molecule ( $\alpha_1$  and  $\alpha_2$  in class I;  $\alpha_1$  and  $\beta_1$  in class II) fold together to form the cleft in which the antigenic peptide can find appropriate lodging (Figure 40-4). These first external domains are approximately 90 amino acids, or 270 base pairs in length. The antigen-combining site (also known as the Bjorkman's groove) is composed of a  $\beta$ -pleated sheet with eight antiparallel strands forming the floor of the groove, and sides assuming the shape of  $\alpha$  helices (Figure 40-5). The amino acid residues forming this cleft are very polymorphic and are particularly immunologically relevant in the  $\alpha$ -helical regions. As the protein folds into the tertiary structure, some of the hypervariable regions assume a location pointing into the cleft (i.e. an optimal position

**FIGURE 40-3** The secondary structure of the HLA class I molecule with the  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$  domains (i.e. amino acid sequences that show similarities and are present more than once in the same polypeptide) of the chain completed by the  $\beta_2$ -microglobulin is here compared with the structure of the class II molecule with its  $\alpha_1$  and  $\alpha_2$  domains of the  $\alpha$  chain. Domains  $\beta_1$  and  $\beta_2$  are characteristic of the class II  $\beta$ -chain only. Both class I and class II heterodimers form, at their most external end, a peptide-combining site composed of the  $\alpha_1$  and  $\alpha_2$  domains for class I, and  $\alpha_1$  and  $\beta_1$  domains for class II molecules. (From Rosner, G.; Martell, J.; Trucco, M. *Histocompatibility*. In Hematopoietic Stem Cell Therapy; Lister, J., Ball, E. D., Eds.; Churchill Livingstone: Philadelphia, 2000, pp 233–251.)

for interaction with the processed antigen). Other hyper-variable segments are instead located on the external part of the molecule and constitute the determinants potentially involved with TCR recognition. These same hyper-variable regions form the molecular basis of alloreactivity in tissue transplantation (i.e. donor differences in these amino acids are recognized as “foreign” by the recipient who immunologically reacts against them). These same, antigenically relevant differences are the HLA originally recognized by Dausset and Payne.

The HLA class I and class II molecules constitute the most highly polymorphic genetic system in humans (24,25). A stable, inherited polymorphism gives rise to alternative forms of the protein, the alleles. Nearly, all

the HLA molecules have various alleles, with HLA-B being the most polymorphic, having on average 86 SNPs per kb (26) and more than 1800 reported alleles, with the numbers consistently rising (27).

The molecular basis for the HLA polymorphism resides in nucleotide sequence differences present in the coding regions of the HLA genes. The polymorphism is clustered into three or four discrete hypervariable regions (Figure 40-6, panel A), which become more evident when the amino acid sequences of these alleles are aligned (Figure 40-6, panel B). These nucleic acid sequence differences account for amino acid differences among the various HLA molecules. Although most HLA alleles occur in all ethnic groups, they may vary in frequency from one group to another (28,29).

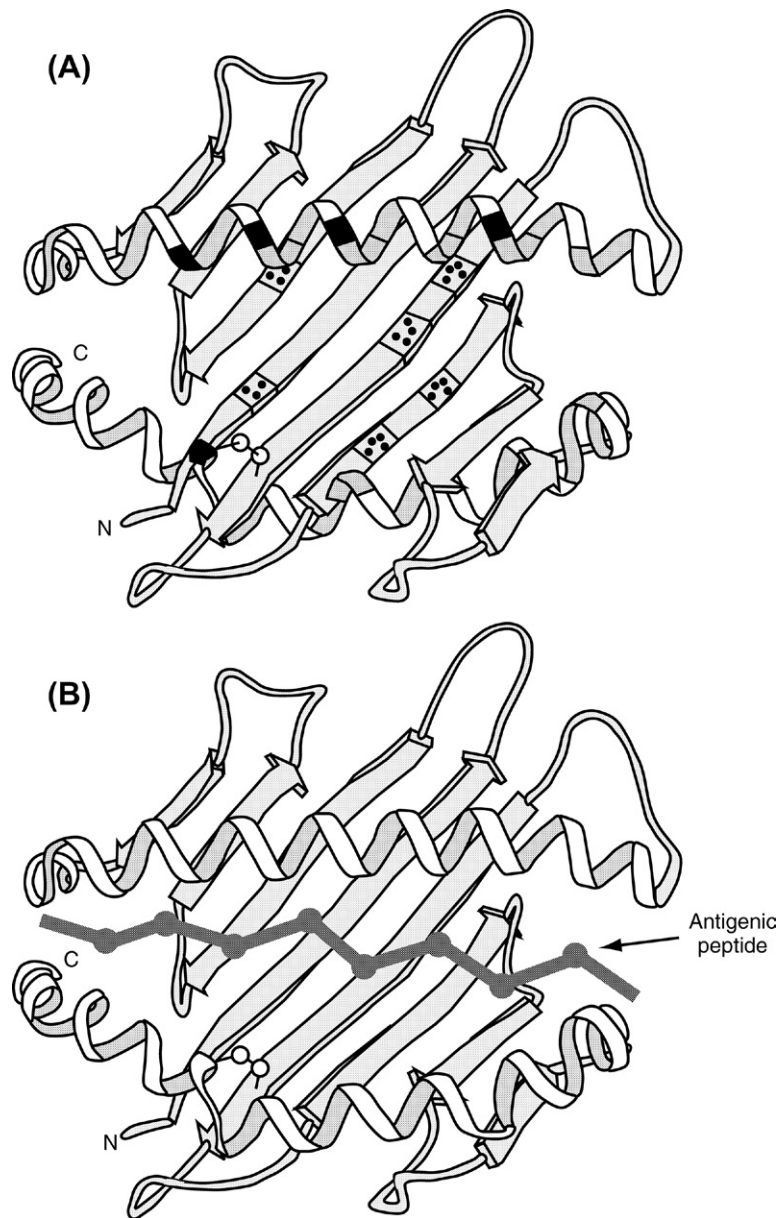

**FIGURE 40-4** The resolution of the structure of crystallized HLA-A2 class I molecule. The molecule, shown here from the side, has its most external domains ( $\alpha_1$  and  $\alpha_2$ ) able to form the antigen-combining site in which the processed antigenic peptide is lodged. In this position, the complex HLA molecule/antigenic peptide is recognized by the T cell via its receptor molecule. (From Faas, S.; Trucco, M. *Major Histocompatibility Locus and Other Genes that Determine Risk of Development of Insulin-Dependent Diabetes Mellitus*. In *Diabetes Mellitus: A Fundamental and Clinical Text*; LeRoith, D., Taylor, S., Olefsky, J. M., Eds.; J. B. Lippincott Co: Philadelphia, 1996, pp 326–333.)

#### 40.4 THE CHROMOSOMAL ORGANIZATION OF THE HLA COMPLEX

The genes encoding HLA class I and class II molecules are located in >4000-kilobase (kb)-long DNA segment present on the short arm of chromosome 6 (26,30,31). This DNA segment can be subdivided into three major regions that encode class I molecules (2000 kb), class III molecules (1000 kb), and class II molecules (1000 kb) (30). The organization of the genes included in the HLA complex is shown in Figure 40-7. The physical location, the locus, of each HLA gene determines its order on the chromosome, while the nomenclature instead recapitulates the chronological characterization of the genes at the various loci. Thus, the A locus is most distant from the centromere and was the first to be characterized. The characterization of the B locus immediately followed that of the A locus, however, A and B are geographically separated by the C locus, which was the last to be characterized. The first class II locus was characterized by cellular tests after C and was then called D. Subsequently, by absorbing out anti-class-I antibodies, sera able to recognize the same alleles defined by mixed lymphocyte reaction (MLR) were also obtained. The alleles recognized by these anti-class-II antibodies were then defined as D related and eventually became known as DR alleles. Class II loci -DQ and -DP were characterized after -DR in this chronological order and actually are in the same physical order on chromosome 6, closer to the centromere than class I loci with -DP as the most centromeric (Figure 40-7). The class I and class II regions are physically separated on the chromosome by genes encoding MHC class III molecules. Class III genes encode components of the complement cascade, C2, Bf, C4A, C4B, the functional steroid hydroxylase gene CYP21, a CYP21 pseudogene, and the genes for TNF- $\alpha$  and TNF- $\beta$  that are not relevant in the context of histocompatibility.

The class I genes present at the A-, B-, and C-loci encode molecules that can efficiently present antigenic peptides once paired with the  $\beta_2$  microglobulin, which is encoded on chromosome 15. The class I region also

**FIGURE 40-5** The antigen-combining site in which the antigenic peptide can find appropriate lodging. In (A), the HLA molecule is seen from the top. The polymorphic regions are indicated in different nuances of color from gray to black. In (B), a schematic, a 9-amino-acid-long peptide is shown present in the groove of the molecule. The antigenic peptides found in HLA class I molecule grooves are normally of this same size, while the antigenic peptides most frequently found associated with HLA class II molecules are longer than nine amino acids and can vary considerably in size. (Modified from Trucco, M. *To Be, or Not To Be Asp 57, that is the Question*. *Diabetes Care* 1992, 15, 705–715).

contains nonfunctional genes (i.e. pseudogenes HLA-H, -J, -K, and -L) and genes that are potentially functional, but whose gene products are not yet fully elucidated such as HLA-E and -F. HLA-G, a protein preferentially expressed at the surface of cytotrophoblasts at the maternal–fetal interface of the placenta, has been shown by Pazmany et al. (32) to sufficiently protect otherwise susceptible target cells from lysis promoted by activated natural killer (NK) cells. In addition to the ones at the -DR, -DQ, and -DP loci, the class II region includes genes encoding proteins involved in antigen processing and in peptide transport from the cytoplasm to the cell surface (33). Besides the large multifunctional proteases and

transporter associated with antigen processing encoding genes, others (i.e. the alpha chain encoding genes—DMA and DOA—or the beta chain encoding genes—DOB and DMB) are present in this region. These nonclassical class II loci likely function by regulating peptide loading onto HLA loci -DR, -DQ, and -DP (34,35).

The class II molecules are heterodimers, that is, molecules consisting of two MHC-encoded polypeptide chains: the  $\alpha$ , (encoded by “A” genes), noncovalently bound to the  $\beta$  (encoded by “B” genes) (Figure 40-3). For -DQ molecules, only the -DQA1 and -DQB1 gene products are expressed as functional -DQ  $\alpha/\beta$  heterodimers. The -DQA2 and -DQB2 genes are pseudogenes

**FIGURE 40-6** In the case of HLA class II molecules, the most polymorphic (i.e. hypervariable) regions between allelic chains are encoded by nucleotides contained in the second exon of the gene (Panel A) corresponding to amino acids 6 through 94 (Panel B). The nucleotides in the sequences are here grouped three-by-three to reflect the amino acid composition of the most external domain of the molecule (i.e. amino acids 6 through 94). In this example, commonly occurring allelic nucleotide sequences of the HLA-DQB1 gene are shown.

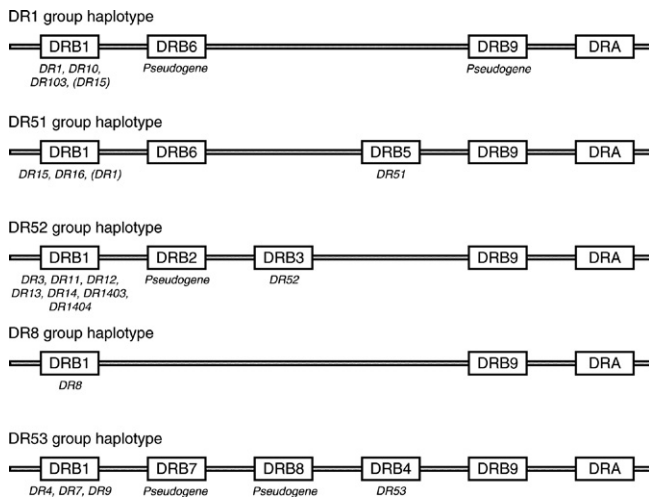

**FIGURE 40-7** The HLA complex present on human chromosome 6, can be subdivided into three regions: class I, class III, and class II molecules. The class II region is closest to the centromere of the chromosome and is conventionally subdivided into three additional subregions, -DR, -DQ, and -DP. In black, are the genes that encode functional molecules; in white are genes that are not functioning (i.e. pseudogenes) or that might encode proteins not yet characterized. The -DRA1 gene encodes a nonpolymorphic  $\alpha$  chain able to pair with the products of each of the functional -DRB genes. In this example, a -DR3 haplotype is shown. -DRB1 gene encodes for the -DR3 allele, -DRB2 and -DRB9 are pseudogenes, and -DRB3 encodes for the so-called -DR52 molecule, which is always found associated with -DR3. (Modified from Luppi, P.; Rossiello, M. R.; Faas, S.; Trucco, M. *Genetic Background and Environment Synergistically Contribute to the Onset of Autoimmune Diseases*. J. Mol. Med. 1995, 73, 381–393.)

(see Figure 40-7). Similarly, only the -DPA1 and -DPB1 genes encode the chains of functional -DP molecules. In contrast, more than one type of -DR molecule can be encoded on the same chromosome, and all are coexpressed at the surface of the same cell. Different -DRB genes are present in different number and in different

combinations on chromosome 6 in different individuals (Figures 40-7 and 40-8). Each type of -DR $\beta$ -chain pairs with the single nonpolymorphic  $\alpha$  chain encoded by the -DRA1 gene (Figure 40-7) (36).

Each individual has one maternal and one paternal chromosome 6, and consequently, one maternal and one

**FIGURE 40-8** DRB genes are present in different numbers and in different combinations on the chromosome 6 of different individuals. While -DRB1 gene encodes the serologically best defined -DR alleles, -DRB3, 4, and 5 encode for three molecules (-DR52, 53, and 51, respectively) always found associated with certain -DRB1 alleles such as -DR3, -DR4, and -DR1, respectively. Thus, -DR51, 52, and 53 are not allelic forms at a certain locus, such as the -DRB1 alleles, rather are different protein products, each encoded by their own genes at different loci, each only present in certain haplotypes. (From Rosner, G.; Martell, J.; Trucco, M. *Histocompatibility*. In Hematopoietic Stem Cell Therapy; Lister, J., Ball, E. D., Eds; Churchill Livingstone: Philadelphia, 2000, pp 233–251.)

paternal allele at any HLA locus. If the maternal allele and the paternal allele differ, as they often do, the person is said to be heterozygous at that HLA locus. If the inherited maternal and paternal alleles happen to be the same, the person is homozygous at that locus. As the maternal and paternal alleles are expressed codominantly, each cell of an individual will express two sets of each HLA molecule (e.g. two HLA-A molecules, two HLA-B molecules, etc.). The combined expression of both sets of molecules constitutes the HLA phenotype of the cells of an individual. The genotype of an individual is instead constituted by two (i.e. one paternal and one maternal) sets of arrays of closely linked genes, many with multiple alleles, inherited as a unit.

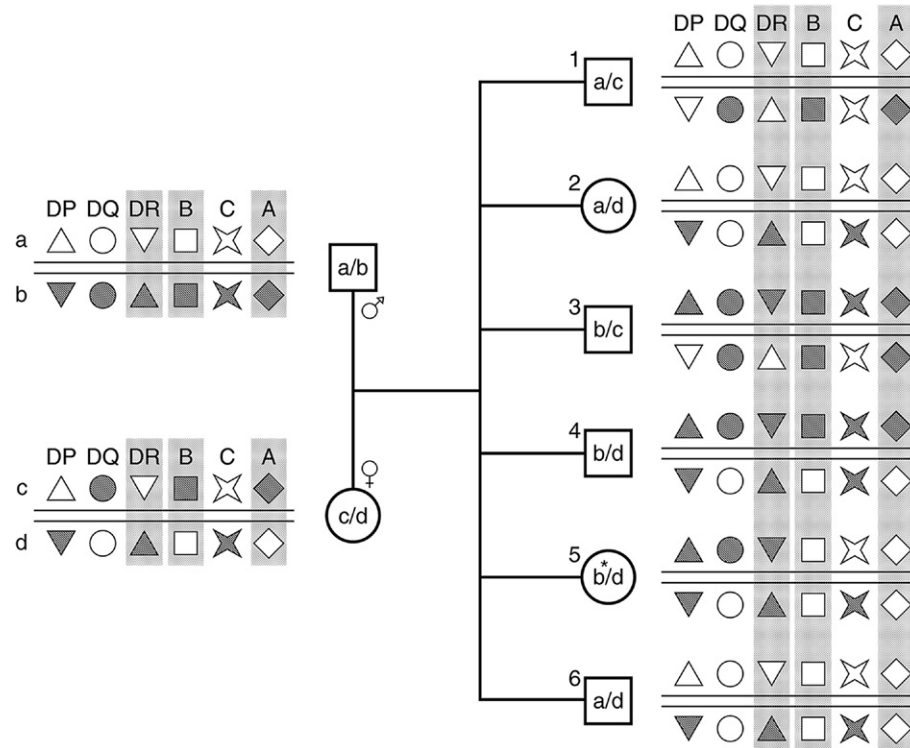

In 1967, Ceppellini coined the term “haplotype” to define each genetic unit inherited from one or the other parent (37). As originally defined, an HLA haplotype includes the class I, III, and II genes present on one chromosome 6 of an individual. The HLA genotype of an individual is composed of one paternal and one maternal HLA haplotype. Each HLA haplotype is transmitted from the parent to the child in Mendelian manner, so that each child shares one haplotype with each parent (Figure 40-9). Within a family, one can find siblings that share two haplotypes (i.e. they are HLA identical), one haplotype (i.e. they are HLA haploidentical), or no haplotypes (i.e. they are HLA different) with the probability of 25%, 50%, and 25%, respectively. Recombination may occur during parental gametogenesis by crossing over during meiosis. However, because of the relative proximity

of the HLA genes, recombination events between loci within a region, or even between regions, though possible, are quite rare. In addition, the selective pressure seems to maintain the genes of each established HLA haplotype together, that is, in linkage disequilibrium (38). With linkage disequilibrium, we define the nonrandom association of the alleles of linked loci present in one haplotype. For example, among Europeans, the most frequent HLA-A and HLA-B haplotype, if we disregard all other loci in the complex, encodes HLA-A\*101g; HLA-B\*801g molecules. This combination occurs in about 9.5% of the population. However, the allele frequencies are 0.172 and 0.125, respectively. If the population were in Hardy–Weinberg equilibrium, that is, noninfluenced by external forces and then in a situation occurring when the genes considered are independently segregating through successive generations, the HLA-A1; B8 haplotype frequency would be  $0.172 \times 0.125 = 0.022$ , or about one-fourth of the observed frequency. In its oldest and simplest measure, linkage disequilibrium, D, can be determined by calculating the difference between the observed haplotype frequency and the expected frequency (39). At equilibrium,  $D = 0$ . Whether or not D is significantly different from 0 is assessed using Fisher’s exact test. If it is significant then LD is said to exist. As a logical consequence, an HLA haplotype composed in part of the paternal and in part by the maternal genes (i.e. a recombinant haplotype) is only rarely observed.

On one hand, recombination is a very rare event across a few generations. On the other hand, it is considered the most efficient mechanism of HLA gene evolution. During the course of evolution, a primitive HLA gene duplicated and mutated; yet, by chance or because of selective advantage, the ancestral complex remained linked. Once gene duplication had occurred, reciprocal recombination was available to generate new haplotype arrangements. Sequence analyses suggest that both intraallelic and intergenic recombinational events were major contributors to HLA diversity (40,41). Some of these events have been likened to the one-way “gene conversion” process, first described in yeast, in which a segment of nucleotides from a “donor” gene is translocated or inserted into another gene (42).

One proposed example of an HLA intraallelic conversion is the specificity -DRB1\*1304 reported by Lee et al. (43). The nucleotide sequence of this allele is identical to that of -DRB1\*1102 except for codons 57, 58, and an intervening sequence that -DRB1\*1304 shares with -DRB1\*0801, \*0803, and \*0405. These authors suggested that one of the three latter alleles donated codons 57, 58, and the intervening sequence to \*1102, which led to serologic reactivity with antisera to -DR13.

A possible example of intergenic conversion is HLA-B46. This allele, which is relatively common in Asian Populations, appears to have derived from the donation of a cluster of nucleotides from HLA-Cw1 into HLA-B62. The donated -Cw1 nucleotides resulted in a

**FIGURE 40-9** With HLA typing we determine the HLA phenotype of an individual. The determination of the HLA phenotypes on at least the two parents and a child or on three HLA-different members of the same family permits segregation analysis, useful to determine the four haplotypes (normally called a, b, c, and d) present in the family, or the genotype of each individual. Consequently, the definition of individuals as heterozygous or homozygous at certain loci (e.g. sibling 1 is homozygous at -DP, -DR, and -C, both alleles are white; but heterozygous at -DQ, -B, and -A loci, 1 white and 1 black allele), together with the recognition of individuals who share one haplotype only (e.g. siblings 1 and 2 share the “a” haplotype, and are HLA haploidentical) or two haplotypes (e.g. siblings 2 and 6 share the “a” and the “d” haplotypes and are HLA identical), or none (e.g. siblings 2 and 3 and are HLA different) becomes possible, as well. A bone marrow transplant always offers the best chance of success if it is performed between HLA identical siblings. “Six-antigen matching” refers to the situation in which two individuals share both alleles at the locus -A, -B, and -DR (gray background) and to the unique situation in which national sharing of kidneys is considered mandatory. In this simplistic example, father and mother are phenotypically the same because they are sharing the alleles at the -A, -B, and -DR loci and constitute a six antigen-matching pair, although they are not HLA “identical,” similar to siblings 2 and 6, because their haplotypes are actually different. Although it is considered a very rare event, it is possible to find individuals, represented here by sibling 5, in which a crossing over between class I and class II gene regions, involving the paternal and maternal haplotypes of the father, cause an a–b recombination flagged here with an asterisk: b\*. (From Rosner, G.; Martell, J.; Trucco, M. *Histocompatibility*. In *Hematopoietic Stem Cell Therapy*; Lister, J., Ball, E. D., Eds.; Churchill Livingstone: Philadelphia, 2000, pp 233–251.)

lack of serologic reactivity with anti-B62 or any other B locus antisera, but an acquisition of reactivity to anti-Cw3 (44). HLA-B46 haplotypes typically carry the -Cw1 gene. If the B46<sup>+</sup> cell is heterozygous at the HLA-C locus, it will type for three HLA-C alleles, -Cw1, -Cw3, and the allele carried on the alternate haplotype.

By convention, the paternal haplotypes are designated as a and b and the maternal haplotypes as c and d. Children in a family are designated as genotypes ac, bc, ad, or bd. If a = HLA-A1;B8;C7;DR3;DQ2;DP4 while b = A2;B7;C7;DR2;DQ6;DP1, and c = A3;B65;C3;DR7;DQ2;DP2, or d = A11;B35;C4;DR1;DQ1;DP4, the phenotype of a child b/d will be A2,11; B7,35; C4,7; DR1,2; DQ1,6; DP1,4, and the recombinant haplotype resulting from a crossing over that took place somewhere in between class I and class II regions of the father’s paternal (a) and maternal (b) haplotypes, will be b\* A1;B8;C7;DR2;DQ6;DP1 as described in Figure 40-9 in simplified terms. Family studies are therefore

recommended, both to confirm the alleles present in each of the patient’s haplotypes and to rule out the possibility of recombination. Only a family study and the analysis of allele segregation can positively elucidate the both haplotypes of an individual.

## 40.5 MINOR HISTOCOMPATIBILITY SYSTEMS

Determining the HLA phenotype of an individual is the goal of histocompatibility testing (i.e. tissue typing) to determine who is a suitable donor for a particular recipient. It can be achieved using serologic and/or molecular techniques (see later and Ref. (45)). Generally, a sibling HLA-identical to the recipient constitutes the first choice as a donor although transplants from haploidentical donors are more frequently being performed today. In fact, although bone marrow transplantation (BMT) between genetically HLA identical siblings has the

highest chance of success, with the declining birthrate in the United States and Western Europe, the likelihood of finding a genotypically identical sibling has dwindled. An estimated 65–75% of individuals requiring BMT will not have a suitable donor in their family (46).

To overcome this problem, alternative sources of hematopoietic stem cells (HSCs) from phenotypically HLA-matched unrelated donors have been sought and used with much success. The National Marrow Donor Program (NMDP) has facilitated unrelated marrow transplants throughout the world, using HLA-matched marrow from donors that were chosen among the volunteers listed in the NMDP registry (47,48). Places such as the Placental Blood Center in New York are also having success with transplants using umbilical cord blood instead of bone marrow cells from HLA-matched and partially mismatched unrelated donors (49–51). Primarily used in pediatric patients, allogeneic cord blood sources accounted for >20% of blood and marrow transplants performed during the years 2004 through 2008. During the years 2006 through 2008, >700 cord blood transplantations were performed annually. Thus far, comparative studies of cord blood and BMT in both children and adults with leukemia exhibit statistically identical outcomes in regard to differences in relapse rates, despite the slower hematopoietic recovery associated with recipients of cord blood stem cells (52).

Unlike related donors who match at all loci within the haplotypes they share, unrelated donors can match at some, but not all loci. Therefore, in order to reduce the risk of graft-versus-host disease (GVHD), precise HLA typing at the various loci becomes essential.

Although to date, clinical experience in transplanting bone marrow from unrelated donors has proved that relatively long-term survival is achievable, the high risks of graft failure and serious, acute GVHD remain major obstacles when compared with transplants between related donors. One plausible explanation for the increased incidence of severe GVHD among allogeneic combinations of donor and recipient is that, unlike genotypically identical HLA-matched siblings who are “identical by descent” for HLA and other poorly characterized MHC or non-MHC (i.e. minor) histocompatibility antigens (53,54), the phenotypically HLA-matched unrelated donors may not be matched for a subset of antigens that can still contribute to alloreactivity (55). Furthermore, recent advances in HLA molecular typing have revealed additional polymorphisms only evident at the genetic level. These differences may have so far still undetermined functional and clinical relevance. The failure to identify these differences using older techniques suggests that unrelated donor/recipient pairs thought to be phenotypically matched, actually were somewhat mismatched (56).

All instances of graft rejection and most instances of GVHD in MHC-identical transplants can be attributed to non-MHC systems. The preponderance of evidence of

their impact on human transplantation comes primarily from BMT (54,57–59). Approximately 60% of patients who receive bone marrow from an HLA-identical sibling will have some evidence of GVHD, and in about 20%, it will be severe. In the mouse, the number of minor histocompatibility (mH) loci has been estimated to be more than 100, about 40 of which have been identified by skin graft experiments and genetic segregation analysis. It appears that the alleles of a particular locus vary in antigenic strength (as determined by mean survival time of skin grafts), and that the effects of different loci are additive (reviewed in Ref. (60)). This is probably true as well in humans because, in general, GVHD increases in severity with decreasing degree of relatedness even with HLA identity.

CTLs have been observed from patients with graft rejection after HLA-identical BMT for aplastic anemia, in multiply transfused patients, and in multiparous women (61–63). In some human and mouse CTL studies, the reactions have shown MHC class I restriction, including H-Y, a minor antigen encoded by a gene on the Y chromosome (53,64–66). Class II restriction of proliferating T cells reactive to mH antigens after HLA-identical BMT have been reported by Reinsmoen et al. (67) and van Els et al. (68). The MHC restriction of T-cell responses to these antigens suggests that they are naturally processed peptides of intracellular proteins that, presumably, associate with MHC antigen-binding sites for presentation to TCRs (59,69). However, not all responses to mH antigens appear to be MHC restricted. For example, as early as 1957, Snell showed that a B10.LP (H-2b) mouse preimmunized with tissue from C57BR (H-2k) rejected a C57BL/10 (H-2b) tumor. All B10.LP mice that were not preimmunized succumbed to the tumor. The tumor donor strain differed from the host only at the H-3 locus, whereas the C57BR strain differs from B10LP at the H-2 complex as well as H-3 and other minor loci. Confirmation that responses to mH are not always restricted was later provided by Murasko (70) who showed that BALB/c (H-2d) mice preimmunized against B10.D2 (H-2d) rejected C57BL/10 (H-2b) skin grafts in an accelerated manner. The interpretation was that the accelerated rejection was against mH antigens, because the preimmunizing strain was H-2 identical to the recipient, whereas the skin donor was not. Inasmuch as the mH loci probably encode a very heterogeneous group of molecules whose structures and primary functions are unknown, it is not surprising that both restriction and nonrestriction have been observed.

In humans, there is indirect evidence of the presence of an HLA-linked mH gene. The first report of this minor locus came from Eisvoogel et al. (71), who observed weak mixed lymphocyte reactivity between siblings, one of whom was a recombinant between HLA-A and HLA-B. This locus, which appeared to map near HLA-A, was designated MLR weak (MLRw). Later, Hsu et al. (72) reported a similar location for genes controlling *in vitro*

cellular responses to the synthetic polypeptides poly(L-tyrosine, L-glutamic acid)-poly(DL-alanine)-poly(L-lysine) and poly(L-histidine, L-glutamic acid)-poly(DL-alanine)-poly(L-lysine). Family studies suggested that the gene, or genes, lie distal to HLA-A. Then, in 1989, in an analysis of 142 HLA-identical sibling donor bone marrow transplants, Hopkins et al. (73) implicated this or a similar locus in the etiology of GVHD. These patients were selected from a total of 323 because they were informative for polymorphisms of clotting factor 13 (F13A), which maps distal to HLA-A, and the red cell enzyme glyoxalase-1 (GLO), which maps proximal to the HLA-D region. No double recombinants between these two loci were observed. Of 68 GLO-informative donor-recipient pairs, 22 were GLO mismatched, that is, one of each pair was a DR/GLO recombinant. There was no significant difference in acute GVHD between the DQ/GLO recombinant and nonrecombinant groups (32% vs 48%). Of 33 pairs informative for F13A, 18 had a donor or recipient recombinant. Among this HLA-A/F13A recombinant group, 67% of the patients had acute GVHD in contrast to 33% of patients in the nonrecombinant group, providing statistical significance to the difference. A relative risk of acute GVHD attributable to this putative immune response gene, that maps near but distal to HLA-A, is 4.0. This, or another, HLA-linked mH locus was described by Vinci et al. (74) who obtained a cytotoxic T-cell line from a patient who rejected bone marrow from an HLA-identical sibling. The cells lysed EBV-transformed B-cells of the donor and some, but not all, unrelated subjects who shared HLA-B44 with the patient. An EBV-transformed line of the patient's pretransplant B-cells were unaffected by the cytotoxic cells.

Neither transplantation nor transfusions elicit much demonstrable antibody production to mH antigens. For this reason, *in vitro* cellular assays, especially the generation of CTLs, has been the method of choice for studying mH antigens in both mouse and man. However, Bias et al. (75) found 31 unique non-MHC lymphocytotoxic antibodies in the sera of multitransfused kidney transplant patients who rejected HLA-identical organs, multitransfused bone marrow transplant candidates whose sera reacted with cells of HLA-identical siblings, and in multiparous women. These sera were tested against cells from 60 families with an average of seven children each. Analysis of reaction patterns revealed that the reacting antigens segregated independently of the MHC.

It is important to note that GVHD, unrelated to histoincompatibility, often occurs in syngeneic or autologous BMT (reviewed in Ref. (76)). It appears that the development of the immune system after BMT is similar to normal ontogeny. It has been shown in animal studies that syngeneic GVHD can be induced by a number of clinical treatments, including neonatal thymectomy, thymic irradiation before engraftment, and cyclosporin treatment for 6 weeks after engraftment followed by withdrawal of the drug. It appears that these treatments cause a

failure of the developing immune system to discriminate self from nonself, resulting in the generation of autoreactive cells, indicating that tolerance to self-antigens is controlled by regulatory T cells. Syngeneic or autologous GVHD is similar to chronic GVHD, a complex of reactions resulting from an imbalance of immunoregulatory cells. In acute GVHD, immunologic recovery occurs when the nonspecific regulatory T cells are able to control autoreactivity. Chronic GVHD appears to be an extension of acute GVHD in which the immune dysregulation continues, resulting in clinical manifestations characteristic of certain autoimmune diseases such as scleroderma.

## 40.6 SEROLOGIC METHODS FOR HLA TYPING

Tissue typing for transplantation refers to determination of the class I and class II specificities (i.e. the HLA phenotype) of both the potential donor(s) and the recipient. Finding the best donor for a kidney transplant generally means finding a "six-antigen match" by looking at each of the two alleles at HLA-A, -B, and -DR loci (Figure 40-9). For bone marrow transplant, however, HLA-C, -DQ and -DP are also typed and often considered (47).

Until recent years, the most largely used serological HLA typing method has been the microlymphocytotoxicity assay (77). This technique uses, as target cells, a suspension of pure and viable lymphocytes that have been separated from whole peripheral blood using density-gradient separation. The lymphocytes are incubated with a panel of alloreactive antisera and a source of complement (C'), usually rabbit serum. The anti-HLA antibodies present in the various sera are quite specific for the individual structural determinants that characterize the polymorphism of the HLA antigens. When a specific antigen-antibody complex is formed, C' activation results in cell lysis. Following addition of a vital dye, the percentage of dead versus live cells can be visualized by phase contrast microscopy. A positive reaction is scored when at least half of the cells are killed. The HLA type is assigned by interpreting the patterns of reactivity of dozens of sera whose specificities are known. Most antisera are obtained from donors who have been exposed by transfusion or multiple pregnancies to cells bearing foreign HLA molecules. As first proved by Rose Payne, multiparous women become immunized against the alleles encoded by the paternal HLA haplotype when blood from the fetus enters the mother's bloodstream at delivery (78,79).

Originally, it was the responsibility of the individual tissue typing laboratory to procure, test, and maintain quality control of the antisera used in testing. The pioneering HLA investigators soon realized, however, the need for standardizing their own reagents. This was achieved by organizing international workshops that have been held every 3-4 years since 1963. These international workshops, originally aimed at sharing and

consequently standardizing alloantisera, target the cells or cell lines, and technical procedures, soon became the forum for recognition of new loci, the definition of new alleles, the adoption of the standard methods, the acceptance and then the use of a common nomenclature.

Today, sera can be obtained locally or through national or international serum exchange programs. Commercial trays with well-characterized sera are most widely used. All accredited histocompatibility laboratories are required to adhere to rigorous standards regarding reagents, protocols, and quality assurance set forth by the American Society for Histocompatibility and Immunogenetics. In addition, most laboratories participate in several proficiency testing programs administered by such agencies as the College of American Pathologists.

However, even with all the refinement and standardization promoted through the years, many problems still confound the results obtainable by serologic methods. As mentioned, serology is encumbered by the requirement for relatively pure populations of viable lymphocytes. This has the greatest impact on class II typing, as HLA-DR, -DQ and -DP molecules are expressed most abundantly on B lymphocytes and less significantly on activated T cells and macrophages, which, all together, comprise at best 20% of the peripheral blood lymphocyte population. Therefore, a relatively large quantity of blood (30 mL) from each individual must be processed in order to obtain enough class II positive cells to allow a complete HLA typing. This may constitute a problem when the individual to be HLA typed is a child. In addition, if the cells are not essentially 100% viable at the beginning of the test procedure as a consequence of disease, chemotherapy, or the consumption of other drugs, the subsequent isolation procedures (e.g. spinning the blood through a Ficoll-Hypaque gradient, collecting cells at the serum/Ficoll interface, and separating B from T cell subpopulations to facilitate the typing of class II and class I alleles, respectively) may further damage them. This cell damage can generate a background of dead cells that, when the cytotoxic reaction is read, will make the results of the specific killing mediated by the antisera and C' indistinguishable from the negative controls. In addition, serology cannot be used to HLA type a patient recently treated with anti-CD3 antibodies, such as OKT3, because these antibodies are cytotoxic in the presence of C' and per se cause cell death, limiting the specificity of the assay. Finally, the C' itself can be a source of variability in these tests as it can, by itself, be slightly cytotoxic.

In leukemias (e.g. chronic myelogenous leukemia) and other disorders, insufficient numbers of B-cells and/or reduced antigen expression can completely preclude class II testing. Although Epstein-Barr (EB) virus transformation (80) and a variety of other procedures have been developed in attempts to procure sufficient numbers of B-cells for testing, they can be labor-intensive, time-consuming, and expensive, besides often being

quite unproductive (81). A major drawback to EB virus transformation is that the blastoid nature of the transformed B-cells makes them overly sensitive to C' activity. Although complement preadsorption with each cell line to be tested can avoid this problem, such treatment is impractical for a general clinical use.

In addition, cross-reactivity (i.e. lack of specificity) of alloantisera still remains an unsolved problem for serological typing. The HLA types defined by serologic methods are often not directly correlated to single alleles. Certain groups of class I antigens belong to cross-reactive groups, which share distinct immunogenic epitopes referred to as public, or broad specificities (82). All the cells sharing a public epitope react with the same antiserum. Further, the antisera used for class II typing are not naturally class II specific. These sera are frequently "contaminated" with class I antibodies, which may cause false-positive reactions. The donor's immune system is exposed simultaneously to the two classes of molecules both present on the immunizing cells. Although extensive absorption with platelets (which express class I, but not class II proteins) can provide a relatively pure preparation of the anti-class-II antibodies, these antisera have generally lower titers and are in shorter supply than anti-class-I antisera.

The need for ongoing screening programs to replenish sera is further complicated, in which two donors will never have exactly the same specificity. In addition, only 200 mL of blood can legally be collected postpartum and even serum obtained from the same donor after subsequent pregnancies can differ with respect to titer or range of reactivity. Accurate serologic HLA typing largely depends on experience and extensive knowledge of protocols and reagents of specialized HLA laboratory personnel.

In 1977, the development of mouse anti-human monoclonal antibodies was seen as the best alternative source to increase specificity and have an unlimited supply of standardized reagents (83). Their use, however, is not yet widespread because of the limited number of "private" specificities recognized by the mouse, which reacts preferentially against "public" specificities. Trays containing only monoclonal antibodies that allow a relatively informative typing are commercially available.

Despite its limitations, the microlymphocytotoxicity test remains the most popular test for clinical use to provide class I and class II typing at a moderate level of resolution in one working day. A drastic improvement in the analysis of percentages of reactive antibodies (PRA) has, however, improved the results of transplant (kidney, in particular) interventions, eliminating the negative conditions frequently found associated with fulminant or hyperacute rejections (HARs). The use of the flow cytometer to determine the presence in the recipient serum of anti-T-cell and anti-B-cell antibodies that are not reactive against the major histocompatibility antigens drastically improved the 4-year graft survival (84).

## 40.7 CELLULAR METHODS FOR HLA TYPING

Other alleles, including those at HLA-C, -DQ, -DP, and perhaps at other loci, are not strongly immunogenic and therefore do not elicit antibodies in large quantity or with high affinity. Reasons could be that these molecules are shed quite rapidly from the cell surface, are in a very limited quantity per single cell, or their critical amino acid differences point into the Bjorkman's groove instead of outside. They may, however, be clinically relevant and detectable by alloreactive T-cells.

As previously mentioned, the first cellular approach successfully used for recognition of HLA class II alleles was the so-called mixed lymphocyte culture (MLC) or MLR. To perform this test, lymphocytes from two individuals are coincubated for several days in tissue culture. If the two individuals are disparate for a class II allele or a non-MHC mH antigen undetectable by serology, both cell types undergo lymphoblastogenesis, synthesize DNA, and proliferate. In the presence of  $^3\text{H}$  thymidine, the degree of newly synthesized DNA can be estimated. Cells that are HLA-identical are nonreactive in MLC, and the incorporation of  $^3\text{H}$  thymidine equals the negative controls.

In 1969, in order to separately monitor the response of the recipient (host-versus-graft) and the donor (graft-versus-host), Fritz Bach proposed to perform two separate unidirectional MLRs (85). The cells chosen as stimulators are irradiated to inhibit DNA synthesis and  $^3\text{H}$  thymidine incorporation. The nonirradiated responders are instead still able to incorporate the thymidine. Every MLC typing test is set up as a complicated matrix of many one-way reactions. In general, three unrelated HLA-mismatched individuals are used as positive controls of the maximum proliferative ability of the responder cells. Every cell should be tested as both stimulator and responder. In addition, autologous controls (i.e. each individual's cells incubated with its own irradiated cells) are used to normalize the response of each cell type to its stimulators. The results are expressed as a relative response (RR) or as a stimulation index (SI). Ideally, when two individuals are HLA-identical, the proliferative responses are <20% of the positive controls (86).

The MLC test has been used most widely in BMT and was developed primarily to help select the most compatible (i.e. least stimulatory) donor when several compatible family members are available (85). It is best used for confirmation of genotypic identity in siblings, especially in cases in which a complete haplotype could not be determined, such as when one parent is unavailable for testing or one appears to be serologically homozygous for -DR or -DQ.

Although the MLC is a cellular cross-match predominantly triggered by class II alleles, it does not define an individual HLA type. One reason could be that

-DR is thought to have dominance over -DQ, perhaps because the expression at the cell surface of the former is 10 times higher than the one of the latter. The role of -DP, with 100 times fewer molecules than -DR expressed on a single cell, remains controversial although recent analysis of HLA-DPB1 mismatches and BMT outcomes suggest an important role (87). This is the reason cellular specificities recognized by MLC testing were originally designated as HLA-Dw ("D" because these specificities were considered to be encoded by a different locus than A, B, and C; "w" because they were still to be officially recognized in the context of an international workshop). HLA-Dw antigens were in reality immunogenic combinations of HLA-DR, -DQ, and/or -DP determinants recognized as such by alloreactive T cells, but not necessarily by alloantisera. By absorbing the antisera with platelets to remove anti-class-I antibodies and using purified B-cells as cytotoxicity test targets, the HLA-Dw determinants were also recognized by certain antisera. They were then defined as D-related serological specificities and eventually -DR alleles.

A variation of this test can be performed in which the lymphocytes to be tested are used as responders in an MLC test, in which a panel of HLA homozygous cells are used as irradiated stimulators. These homozygous typing cells (HTC) are able to define the HLA-Dw specificities but are quite difficult and costly to procure. Inasmuch as the majority of HTC are EB virus transformed cell lines, the results of the testing is frequently difficult to interpret. Other available cellular tests are the primed lymphocyte test, frequently used to better identify -DP alleles, and the cell-mediated lympholysis test, which primarily reflects the stimulatory and effector functions of CTLs in culture (88,89). Although proved extremely useful for research purposes, these tests are too complex and the results are too difficult to standardize to be included in routine typing procedures.

Until recent years, the convention was to use HLA-A, -B, and -DR serology (i.e. six antigens matching) to select a donor, with the MLC as the final arbiter of donor-recipient compatibility. In addition, a pretransplant cross-match of patient's serum against donor lymphocytes (i.e. PRA determination) is generally done to ensure that there is no recipient presensitization to donor HLA antigens, which could prevent engraftment. However, the MLC lacks sensitivity and specificity, in particular, when used for patients with hematologic disorders. Spontaneous proliferation of malignant blast cells in culture and/or poor HLA antigen expression can contribute to false positives or false negatives, respectively. The MLC is technically difficult and as many as 40% of the tests are uninterpretable. Furthermore, it does not have good predictive value for either rejection or GVHD. Therefore, despite being the only functional test for assessing class II histocompatibility, the NMDP no longer requires it before performing a bone marrow transplant (90).

## 40.8 MOLECULAR METHODS FOR HLA TYPING

The practical limitations of both serologic and cellular assays, as well as their inability to resolve clinically relevant subtypes, prompted the rapid development of molecular biologic techniques for HLA typing. Molecular techniques can precisely define differences missed by serologic typing and/or those suggested by an incompatible MLC.

In the 1980s, molecular biology technologies, such as gene cloning and sequencing, became simple to perform. This facilitated the isolation and characterization of the HLA genes at different loci from hundreds of individuals. By comparing sequence variations from person to person, the nature and locations of the polymorphism of the HLA complex were revealed (Figure 40-6).

The initial attempts to perform molecular HLA typing were based on restriction fragment length polymorphism (RFLP) analysis (91). RFLP testing uses a specific DNA probe to recognize the presence of a certain HLA gene on a set of DNA fragments. These fragments are generated by digestion of genomic DNA with commercially prepared bacterial restriction endonucleases (i.e. restriction enzymes) that recognize short, specific nucleotide sequences. The resulting array of restriction fragments are separated on agarose gels by electrophoresis, transferred by capillary action to a nitrocellulose or nylon membrane (Southern blotting), and sequentially hybridized with radiolabeled DNA probes specific for each HLA locus. After repetitive washings, the radioactive probes specifically hybridized to their DNA fragment are revealed by exposing the membranes to X-ray film. The positive fragments differ in size and number from an individual to another, thus creating a polymorphism useful for typing. Although by RFLP it was possible to generate results more precisely and completely than serological typing (92,93), in some laboratories, the use of radioactivity was problematic in that high-quality Southern blots could not be achieved. Also, the turnaround time for even a small number of tests was very long, thus precluding the use of these DNA tests in a clinical setting.

The Xth International Histocompatibility Workshop was organized with the specific aim of transferring RFLP technology to laboratories specialized in HLA serology. All participant laboratories received a common set of HTC lines and a panel of DNA probes. Although the proceeds of this workshop, published in 1987, were useful in establishing standards for RFLP analysis of class II loci, and the collective data obtained revealed strong associations between certain -DR and -DQ alleles and the RFLPs (94), the results were not definitive, largely because of strong homology and cross-reactivity between different alleles and even different loci. These obvious limiting aspects did not preclude, however, their application to fulfill specific aims, such as the characterization of HLA-DQ alleles that confer susceptibility to

type I diabetes (95), or the comparison between serologic and molecular typing in promoting kidney graft survival (96,97). As other techniques that directly analyze HLA polymorphism were being developed, RFLP analysis was, however, quickly deemed unsuitable for general clinical use.

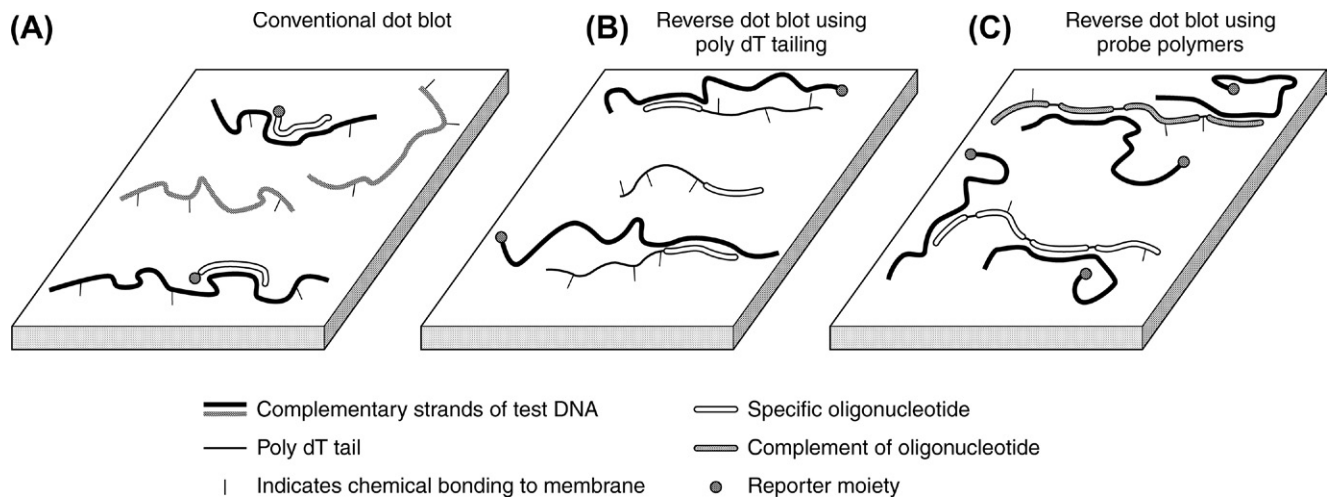

The introduction of polymerase chain reaction (PCR) (98,99) during the late 1980s revolutionized HLA molecular typing. PCR is a powerful and versatile technique for generating millions of copies of specific genomic DNA fragments from minute amounts of starting material once the nucleotide sequence of a certain gene is known. Amplification is accomplished automatically in a DNA thermal cycler by incubating nanogram quantities of DNA, isolated from any possible source in solution with buffer, free deoxynucleotide triphosphates (dNTPs), specific oligonucleotide primers, and thermostable DNA polymerase. The most common of analyses are performed by dot blotting a few microliters of the amplified DNA onto replicate nylon membranes. Each membrane is then hybridized with a different sequence-specific oligonucleotide probe (SSOP) labeled with a reporter moiety. After washing away the unbound excess, the retention of specific probe can be visualized by a variety of methods, the most common of which is chemiluminescence (Figure 40-10A). This approach allowed typing of hundreds of samples with a relatively small number of probes to determine, for example, that variants of sequences involving codon 57 of the second exon of the HLA-DQB1 gene were reliable markers for insulin-dependent diabetes mellitus susceptibility (100,101).

As the extremely large sequence diversity of the class II gene second exon was revealed, the possibility of using this technique for complete HLA class II typing seemed difficult, yet feasible. This daunting task was promoted and organized by the XIth International Histocompatibility Workshop, which provided standardized conditions and a battery of probes to each of its participant laboratories (102).

The advantages of this technique, often referred to as “oligotyping,” are many (Figure 40-10A). The requirement for viable, purified lymphocytes expressing HLA antigens is eliminated. Reagents can be standardized and synthesized in unlimited quantities. Functionally relevant subtypes and polymorphisms as small as one nucleotide substitution can be precisely defined as stringency conditions for hybridization can be perfected for each probe. However, to provide a high-resolution HLA typing, up to seven separate PCR amplifications may need to be done for -DRB and -DQB1 typing alone. A complete set of results, no matter how large or small the set, required 4–5 days to be finalized.

Therefore, this technique is not well suited for routine clinical applications, in which a relatively small number of samples should be tested as quickly as possible.

A different format referred to as the “reverse dot blot” has proved advantageous in reducing the amount

**FIGURE 40-10** “Conventional” dot blot used in SSOP typing (A) is compared with reverse dot blot after poly(d)T tailing of the various probes (B), and with reverse dot-blot of polymeric probes (C). (From Rudert, W. A.; Trucco, M. *A Novel Approach for a Rapid HLA Class II Molecular Typing*. In *Histocompatibility Testing*; Tsuji, K., Aizawa, M., Sasazuki, T., Eds.; Oxford University Press: New York, 1992, pp 352–356.)

of technical manipulation and in improving turnaround time (103,104). Reverse dot blots feature a premade membrane to which the entire battery of probes has been fixed. The DNA to be tested incorporates the reporter moiety during amplification and is then hybridized against the probes present on the membrane. Advantages include labeling one or few DNA samples per donor instead of many probes, performing an entire test with only one membrane, and obtaining results in one working day.

The canonical size of specific oligonucleotides normally used as probes is about 20 nucleotides, a size that has been determined as best for discriminating even 1 bp change. For the reverse dot blot, the direct attachment of probes of this size is inefficient and involves formations of chemical bonds to portions of the probe, resulting in reduced hybridization capability. These difficulties have been solved by enzymatically adding a large number of thymidine nucleotides to the end of the probe (poly dT tailing) (104). The increased length facilitates binding efficiency and favors formation of chemical bonds in the poly dT tails, thus leaving the sequence-specific parts of the probe available for hybridization (Figure 40-10B). This approach is being used in some commercial kits for HLA typing.

An alternative method (103) uses a different approach to bind nucleotide probes to the membrane. Long polymers, usually >25 repeats of the specific nucleotide sequence, are synthesized and bound to the membrane with high efficiency (105). Although chemical bonds between the membrane and the DNA will prevent the hybridization to some sequences, the result is that many more specific sequences remain available for hybridization. Another advantage of this method is that both complementary strands of probe sequence are bound to the membrane (i.e. the probes are double-stranded). This allows both strands of amplified DNA to hybridize to

the probe, further increasing the sensitivity of this assay (Figure 40-10C). Finally, a large quantity of polymers of the same size can be generated from those cloned into plasmid vectors. This level of reproducibility is not obtainable with poly dT tailing and would permit standardization of this technique for intralaboratory use.

Other “reverse” techniques involve fixing probes to 96-well plastic trays with either colorimetric or fluorescent detection (106,107).

Another technique based on the use of sequence-specific primer (SSP) pairs and PCR has been proved more suitable for clinical use. SSP consists of a battery of primer pairs, each capable of only amplifying a specific gene segment. The numerous PCR products obtained are then loaded onto an agarose gel. After electrophoresis and staining, the presence of the specifically amplified DNA segments can be visualized on a UV lightbox, so as to allow correct allele definition. The presence of determined band combinations allowed the attribution of each allele. SSP offers the possibility of obtaining moderate- to high-resolution HLA typing in a few hours. Techniques for -DRB molecular typing using 32 sequence-specific pairs of primers (108) and -DQB1 typing using 14 primer pairs (109) have been published. Several commercial companies offer SSP testing kits.

Both SSP and SSOP methodologies have also been applied to class I typing, which is proving to be a much more formidable task because of the high degree of widespread polymorphism compared with the class II genes and the complications presented by the presence of pseudogenes. One method for SSP typing (110) uses nine coding-strand and seven noncoding-strand primers in various combinations to generate HLA-A specific amplification products. The specificity of PCR priming is increased by taking advantage of the amplification refractory mutation system (ARMS), in which nonspecific reactions are inhibited by introducing a nucleotide

mismatch near the 3' end of the primer (111). Fifteen HLA-A group specificities can be successfully characterized using this method, which appears to be comparable to routine serology with respect to identification and resolution of HLA-A specificities. Subtypes of each group can be more specifically resolved using additional primer pairs (112). Low-resolution typing of the HLA-B alleles has also been described (113) using a similar approach. Twenty-four PCRs using 34 primers are sufficient to determine the majority of, but not all, serologically defined specificities at the HLA-B locus. ARMS-PCR has also been used to detect alleles at the HLA-C locus (114).

The SSP approach is especially amenable for use in clinical laboratories that do not have a great deal of molecular biology experience as the equipment and special techniques required are minimal. Because from DNA extraction to allele identification, reliable and easily interpretable results can be generated in <4 h, SSP typing is an especially attractive alternative to serology for clinical laboratories. However, for laboratories performing large-scale molecular typing, the SSP method may not be amenable.

Substantial progress has been made in converting the methods for molecular HLA typing to microchip technology (115–118). For example, working with HLA-B as a model system, an oligonucleotide array has been used to identify alleles occurring within a set of 100 samples obtained from unrelated individuals (116). Probes were optimized that represented all known polymorphisms encoded in HLA-B exons 2 and 3. Hybridization of PCR products allowed unambiguous detection of complex heterozygous SNP combinations, including some (e.g. HLA-B\*1502+\*2702 and HLA-B\*1513+\*2708) in which combinations of nearby SNPs cause ambiguous genotyping results when analyzed by conventional sequencing-based methods. More recently, the International MHC and Autoimmunity Genetics Network has exploited parallel genotyping of 1472 SNPs using microarrays to determine complete HLA class I and class II genotypes from more than 10,000 subjects (119). The accuracy of the method for determining 2- and 4-digit resolution at HLA class I and II loci has been estimated to be as great as 95% (118). Among its advantages, microarray technology can potentially accommodate thousands of perfectly distributed DNA spots on microarray platforms where hybridization can take place, saving reagent quantities, avoiding time-consuming manipulations, and providing automatically read results. Moreover, oligonucleotides-array-based strategies can provide high-throughput genotyping by virtue of parallel analysis of multiple genetic regions (115,119). A limitation of the microarray-based method, however, is the need for sophisticated, robust data handling protocols that are likely out of reach of the typical clinical typing laboratory. Thus, current use of this approach is limited to genome sequencing centers and a handful of specialized laboratories with interest in the HLA region.

In contrast to the microarray approach, microsphere technology has been widely adopted by the HLA typing community. The method exploits the use of color-coded beads developed in order to advance DNA hybridization-based typing methods (120). The major components of the system are benchtop flow cytometer, two-color microspheres, and biotinylated PCR-amplified product for probing specific oligonucleotides attached to individually color-coded beads. Flow cytometry analyzes individual microspheres by size and fluorescence, distinguishing three fluorescent colors (i.e. green at 530 nm, orange at 585 nm, and red at wavelengths above 650 nm). The ratio of two of the fluorescent signals is used for microsphere classification so that different two-color-coded beads, pre-labeled with probe DNAs, can be identified along with a third fluorescent signal to be used for quantification of hybridization signal. In this methodology, first applied toward HLA for genotyping of HLA-DQA1 alleles but later applied to class I as well as HLA-DRB1, -DQB1, and -DPB1 alleles, targeted DNA is PCR amplified using group-specific biotinylated primers (120–122). The biotin-labeled PCR product allows detection of hybridization between probe and amplified sequence by using R-phycoerythrin (PE)-conjugated streptavidin. Flow cytometry analysis enables quantification of the fluorescent signals on each microsphere. Assignment of HLA genotype is based on the hybridization reaction pattern compared with the pattern associated with published HLA gene sequences. In this manner, it is conceptually similar to traditional hybridization-based HLA typing approaches. At present, up to 100 individually color-coded microspheres, each containing a different allelic oligonucleotide probe, can be analyzed in a single mixture of oligonucleotide-coupled microspheres. The HLA loci are amplified from genomic DNA using sequence-specific oligonucleotide primer mixes that are optimized for PCR amplification of particular HLA alleles and have been used with dried blood spots as well as DNA isolated from blood draws and buccal swabs.

Advances to sequence-based typing methods have been applied to HLA genotyping. Pyrosequence-based typing (PSBT) has been developed to allow accurate sequencing of short stretches of DNA, initially for the analysis of expressed sequence tags (123,124), and has been applied to HLA genotyping (125–131). Sequencing of lengths between 50 and 150 nucleotides has been reported during analysis of HLA genotypes of loci HLA-DQB1 and HLA-DR. The method is suited for use during SNP analysis of HLA because of its ability to accurately resolve heterozygous nucleotides by enabling out-of-phase sequencing (130,132). Pyrosequencing is performed by addition of dNTPs individually in a predefined dispensation order, so that the nascent nucleotide chain is extended one nucleotide residue per dispensation event. Detection of nucleotide sequence is performed by way of a chain of enzymatic reactions involving the activities of

DNA polymerase, apyrase, ATP sulfurylase, as well as luciferase, respectively, allowing for the incorporation of complementary nucleotide, degradation of unused dNTP, generation of luciferase substrate from pyrophosphate and adenosine 5'-phosphosulfate, and emission of light from the ATP-driven conversion of luciferin to oxyluciferin (123,133). Incorporation of a particular nucleotide is displayed graphically in the form of a chart recording of nucleotide dispensation event versus the intensity of emitted light. This cascade of enzyme reactions is quantitative, in that increased light intensity is produced upon incorporation of multiple nucleotides (134).

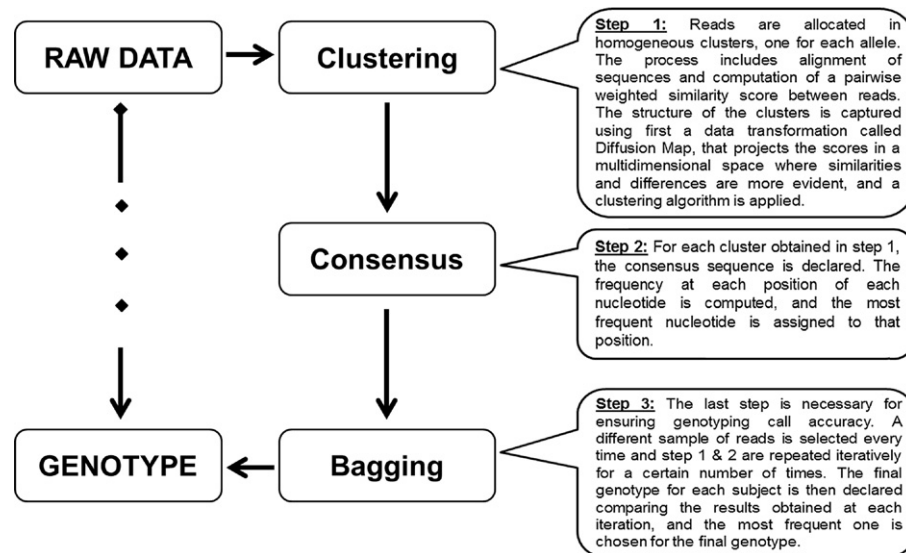

PSBT provides distinct advantages for genetic typing in that samples can be assayed in 96-well trays making it compatible with common laboratory automation instruments, thus increasing the rate of sample analysis, and the sensitivity of the technology requires little PCR-amplified material for each sequencing reaction (123). PSBT strategies can be designed using a minimal number of nucleotide dispensation events, so that an entire 96-well tray can be assayed at a rate of roughly 1 min per base and approximately 20 min for a 20-nucleotide sequence, sufficient for analysis of most HLA alleles when primers are placed adjacent to polymorphic regions. Moreover, out-of-phase pyrosequencing of alleles (130,132) allows unequivocal genotyping of allelic combinations that are ambiguous by conventional sequence-based typing techniques as well as those spaced too far apart to allow resolution by hybridization approaches (Figure 40-11). This results from the pyrosequencing system accepting nucleotides individually at each dispensation event, which directs the phase of primer extension of individual alleles. Out-of-phase pyrosequencing enables the detection of sequencing signal from each haplotype individually. This, in turn, enhances the ability to distinguish between genotypes for allelic combinations involving polymorphisms associated with crossing-over events (125,129,130). These sequences can be determined with greater accuracy because they can be sampled at multiple independent dispensation events tailored to provide allele discrimination from each haplotype.

In the past few years, pyrosequencing technology has advanced substantially allowing it to be used as an important method within the stable of next-generation sequencing technologies (135). The method was reengineered by the 454 Life Sciences in ways that enable efficient preparation of thousands of individually prepared clones for analysis within a single sequencing run, scaling of the reaction to picoliter volumes, and increasing read lengths to as great as 400 nucleotides. As the length of the polymorphic exons of HLA class I (exons 2 and 3) and class II loci (exon 2) are between 264 bp for HLA-DPB1 exon 2 and 276 bp for exon 3 of HLA-A, -B, and -C, the reengineered pyrosequencing method is capable of sequence-based typing of HLA alleles. In fact, a number of research laboratories have already reported achieving high-resolution typing of HLA class I and class

II loci using genomic DNA isolated from human cell lines as well as blood samples (136–138) and from cDNA created from isolations of mRNA (139). The main focus of research is now concerned with preparing high-quality template from DNA obtained using typical patient samples, including venous blood draws, dried blood spots, and buccal swabs, with the latter two examples being especially challenging to prepare because of the small amounts of DNA that are typically obtained. Along with translating the methodology from the research-based setting to the clinical HLA-typing laboratory, there is great need to develop computational methods for analyzing the data (138). For example, using only half of the 454 sequencer's capacity, Galan et al. (140) reported obtaining complete HLA-DRB exon 2 sequencing from 1407 samples. This resulted from analysis of >220,000 sequence reads and required substantial computational support in order to organize the data by subject, align the sequences, and identify the alleles involved. It seems likely that some of the alignment and assembly methods developed for the human genome project (141) along with advanced statistical methodology for sorting data obtained from heterozygous subjects will be required in order to fully achieve the goal of using next-generation sequencing as a paradigm for routine HLA typing (142,143). Given the proven ability of the methodology to generate high-resolution HLA typing from thousands of samples in a single-sequencing run and at low cost, these final hurdles will no doubt be overcome in the near future.

For example, a review of the literature revealed the availability of software for genotyping of HLA alleles using data generated by the 454 next-generation sequencer. The first is the CONEXIO ATF, which was used in a study conducted by Holcomb et al. (143), where the same set of genomic DNA samples were analyzed by eight different laboratory sites, and the results compared, showing the consistency of so-called the genotype. Although the methodology underlying the CONEXIO was not fully explained, it seems likely that the main step is the identification of the most abundant sequences generated, followed by assignment of the HLA genotype. The second HLA-typing algorithm was developed by Elrich et al. (142) and integrated the Genome Analysis Toolkit (GATK), a data processing tool for next-generation sequencing data (144). Given samples from heterozygous subjects, this methodology focuses on computing the posterior probability for all possible pairs of four-digit HLA alleles and assigns, as the genotype, the most likely pair. In particular, the posterior probability is computed as the product of the genotype, the phase and the frequency probability. The genotype probability is defined as the product of the probabilities of observing a base at a particular position given the data, as determined by GATK. The phase probability is computed as the product of the binomial probabilities that the phase orientation for each allele pair is consistent

**FIGURE 40-12** Clustering and Alignment of Polymorphic Sequences (CAPSeq) is a software application designed to genotype MHC alleles. Using next-generation data as input, the application enables clustering of similar sequences (i.e. those reflecting different alleles present in a heterozygous individual) and generation of a consensus sequence for each cluster. The consensus sequences are then compared with a list of known HLA allele sequences in order to identify the best match. The process is repeated in an iterative fashion using statistical method “Bagging” in order to increase the accuracy of the genotype call.

originating from pseudogenes). Diffusion maps are used to measure the “connectivity” of a dataset. The data are projected into diffusion space, in which the Euclidean distance between two points is small if the points are highly connected in the original feature space and large otherwise. Diffusion distance is a robust, non-linear measure that preserves the intrinsic structure of the data; which makes it an ideal choice for clustering problems involving related but highly polymorphic DNA sequences. Then the Kmeans algorithm is applied and the reads clustered in homogeneous groups. In the second step, the consensus sequence for each cluster is established by majority rule at each position. The genotype is called by comparing the consensus sequence with that of previously known HLA allele sequences. The third step is performed for ensuring classification accuracy. To this end, bagging (147), bootstrap aggregating, is used. Bagging is a machine learning technique that generates multiple versions of the same predictor, taking an “average” as final result. In the present example, it consists in sampling a fraction of reads from the total number of reads available, while performing steps one and two in an iterative manner. The process is repeated  $N$  times, and the final genotype declared by majority rule.

## 40.9 CLINICAL SIGNIFICANCE OF HLA MOLECULAR TYPING

A possible criticism to DNA typing is that it gives “too much” information. Although it has been hypothesized that even one nucleotide difference, and hence one amino acid disparity, can result in increased risk of alloreactivity in vivo (148), many nucleotide substitutions do not cause amino acid changes. Given the huge number of

detectable alleles at the various loci, it would be important to determine which mismatches are allowable and which ones are instead nonpermissive for a positive clinical outcome.

A number of studies have been done to determine the clinical impact of HLA matching in unrelated bone marrow transplants. Many reports have shown that the incidence of both acute GVHD and rejection are significantly higher among patients transplanted with phenotypically matched bone marrow cells from unrelated donors compared with cells from genotypically identical siblings (149,150), in particular when serologic techniques were used for HLA typing (151). Further, the incidence and severity tend to increase with increasing HLA mismatch, except in very young patients, in whom one HLA locus mismatch can be tolerated (152).

As described in a recent review (153), patients with acute myeloid leukemia can be favorably treated by BMT when paired with mismatched killer Ig-like receptors (KIR) and one HLA class I allele (154,155). Occurring in haploidentical BMT, the phenomena is believed to result from a failure to suppress NK cell killing when KIR-HLA class I mismatches occur (155). Reduced incidence of leukemia relapse results from NK cell cytokine-induced killing of recipient patient tumor cells and is regulated by the reduced KIR-HLA class I interaction between NK cells and mismatched target cells. In these cases, only one of the donor HLA-carrying chromosomes is matched with recipient, resulting from situations in which either parents or siblings matched at only one chromosome provided donor marrow. Under these conditions, a KIR-HLA class I mismatch will present and a fraction of donor NK cells will express KIRs not able to engage the HLA class I alleles of the recipient, thus

having the potential to kill the patient's leukemic cells (154–156). Mismatched NK cells do not cause GVHD, possibly because nonhematopoietic tissues may not express NK receptor activating ligands.

Bone marrow transplant is a case apart in general tissue transplantation because drastic immunosuppressive regimens cannot be applied as they are for any other type of organ to be transplanted. Immunosuppressive therapy is necessary to prevent graft rejection even when donor and recipient are HLA-identical siblings. It is the effectiveness of the immunosuppressive therapy that permits the survival, often for many years, of allogeneic grafts, many of which are poorly HLA matched. There is an abundance of data that show little or no difference between well-matched and poorly matched grafts as measured by 1-year survival (157). These considerations, added to the need for transplantation in a relatively short amount of time for the most severely diseased patients and to the limited number of donor organs available, have lead many to propose that organ allocation should be governed primarily by criteria other than HLA matching (158). This discussion was particularly contentious in those days (159–161). However, if we consider a longer time of transplanted organ survival, we can see how HLA matching of donors and recipients may actually have a relevant effect. In 1992, Terasaki et al. (162) developed logarithmic plots predicting 10-year rates of graft survival and rates of loss in organ half-life. They compared these predictions with actual graft survival of transplants done from 1975 to 1980. Their half-life actuarial estimate of 16,320 first cadaveric kidney grafts from the United Network for Organ Sharing (UNOS) registry was 10.3 years. From the 1975–1980 actual 10-year survival data, they calculated a half-life of 24.0 years when the donor was an HLA-identical sibling, 11.8 with a parental donor, and 7.9 with a cadaveric donor. When the cadaveric donor grafts were evaluated by HLA matching, the half-life was 19.7 for no -A, -B, -DR mismatch (or 6 antigens match) and 7.5 years for complete mismatches. The estimated half-life was similar though for one, two, three, four, and five mismatches. All other variables analyzed did not make any difference, including race, sex, original disease, and other nonhistocompatibility factors. On the basis of their conclusion that “HLA matching is the single most important factor that can improve nationwide 10-year graft survival rates,” the equitable system of organ allocation approved by UNOS was the following: the priority system adopted for nonrenal patients included the length of the time a patient has been on the waiting list, the severity of his or her illness, and the proximity of the available organ to the patient. For kidney allocation, the degree of HLA matching and the degree of HLA presensitization (i.e. PRA values or presence of antibodies against donor HLA specificities)

were added to the above criteria (163). UNOS has also mandated national sharing of perfect HLA matches, irrespective of other criteria. The probability for a kidney patient to find a perfect match anywhere is, however, no more than 5%.

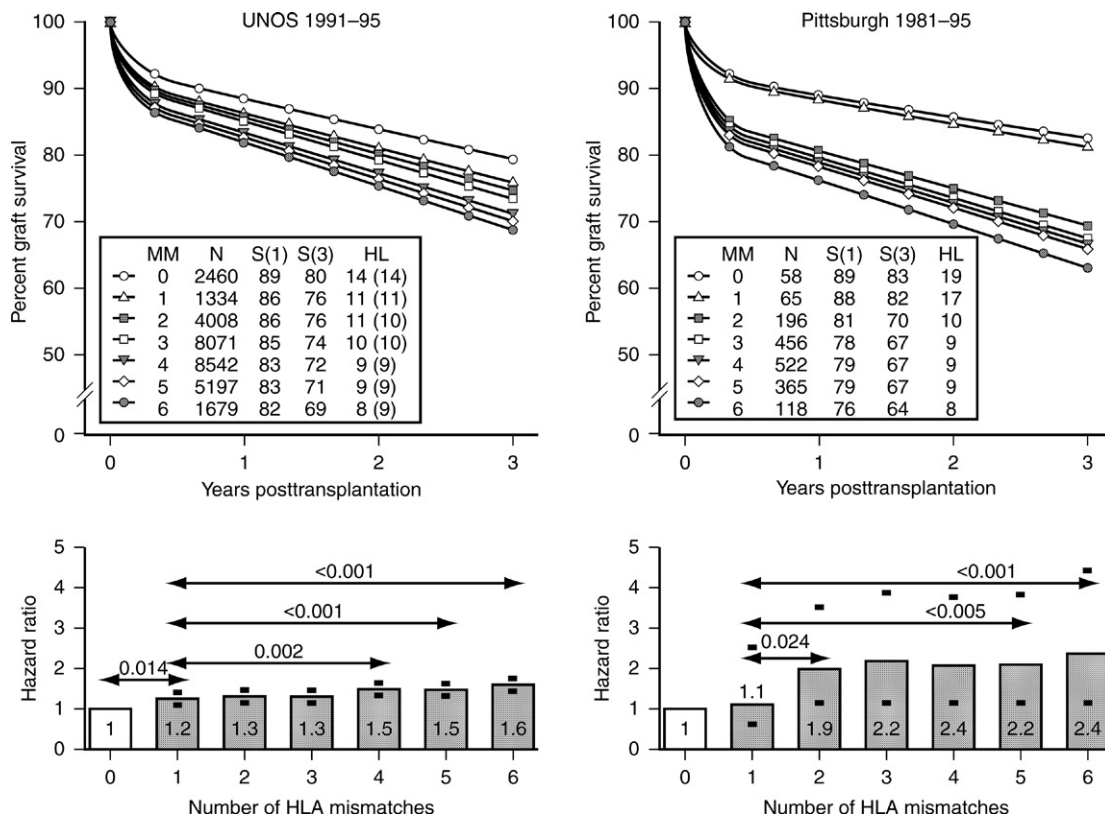

The results presented by Opelz et al. (164,165) relative to the cumulative results from various European transplant centers seem to confirm the appropriateness of these criteria. Starzl et al. (166), using updated results obtained from UNOS registry, have also proved the importance of HLA perfect matching for kidney transplants although the negative effect of mismatches seems to be the same for more than one or all the six alleles and limited to a small percentage even in a 10-year survival analysis (Figure 40-13). This is the reason why all kidney patients are still typed for HLA and ABO blood groups before entry in to the waiting list and their sera screened for anti-HLA antibodies.

With the advent of DNA methodologies for HLA typing, it has been proved that unrelated donors who appeared HLA-identical by serology were indeed not matched at the DNA level and that really matched pairs survived much longer. Studies using DNA methods for both class I and class II (167) typing have shown that molecular matching may reduce the risks of acute GVHD and patient mortality.

The likelihood of finding a matched donor in the registries also depends on whether the patient has a common or rare HLA genotype. Not only are some alleles more common or rare within a particular ethnic or racial group, but because of linkage disequilibrium, certain alleles can give rise to different haplotypes within different populations. NMDP is making an extraordinary effort to enroll in its registry HLA molecularly type different minority groups so to increase the likelihood that minority patients requiring any type of transplant, particularly kidney or bone marrow transplants, can find a more suitable HLA-matched donor.

Even considering all the possible genotypically identical siblings as donors and the large number of potential donors enrolled in the NMDP registry, still a substantial number of patients will not be able to find an HLA-matched donor. In addition, as the discovery of new loci and alleles that potentially must be matched increases, the odds of finding a complete match will decrease even further. Therefore, the most important charge for those involved in BMT is a more precise definition of HLA mismatches that are clinically permissible versus those that are functionally significant with respect to rejection, GVHD, and overall patient mortality.

The transplantation of organs other than bone marrow or kidney offers, however, a completely different scenario inasmuch as the patients are routinely transplanted on the basis of their serious clinical conditions that impose this type of intervention to be

**FIGURE 40-13** Survival percentages of kidney transplants subdivided by 0 to 6 HLA antigen mismatches (MM). (From Starzl, T. E.; Eliasziw, M.; Gjertson, D., et al. HLA and Cross Reactive Antigen Group (CREG) Matching for Cadaver Kidney Allocation. *Transplantation* 1997, 64, 983-987.)

performed as soon as an organ becomes available. The HLA typing is generally performed a posteriori and the presence of reacting antibodies in the recipient only used to modify the immunosuppressive regimen. The possibility to successfully transplant organs such as the liver across the histocompatibility barriers seems to be due to the intrinsic characteristics of such a large human gland (168). First, the liver is able to absorb a large quantity of antibodies without having its function impaired; second, the quantity of immunocompetent cells present in the liver at the moment of the transplant is considered, by some, the possible reason for the liver's tolerogenic power. Under the protective umbrella of immunosuppression, immunocompetent stem cells present in the liver are able to migrate into the recipient body where they are not strongly confronted by a drug-impaired immune system of the recipient. In this peculiar context, the immune system of the recipient may become "accustomed" to the presence of immunocompetent cells of the donor, so that both systems harmoniously survive in the transplanted individual. This exceptional situation known as immunologic chimerism (Figure 40-14) can offer the invaluable advantage of generating a donor-specific type of tolerance in the recipient that *ipso facto* becomes able to host the foreign tissue without the need of a massive and,

in general, particularly dangerous immunosuppressive regimen. These types of considerations were actually supported by the finding of immunocompetent cells of donor origin in the tissues (e.g. skin) or in the blood of patients who received a liver transplant before 30 years (157,158,169-171). In different proportions, a certain degree of immunologic chimerism, or a "microchimerism," was also found in kidney and heart transplant patients years after transplantation (171). The enthusiasm produced by these incontrovertible findings promoted the implementation of therapeutic protocols aimed at favoring the establishment of immunologic chimerism. One protocol suggested the augmentation of immunocompetent cells obtainable by cotransplanting with a solid organ not generally rich in these cells (similar to the heart or the kidney), the bone marrow cells from the same donor (172). Although this therapeutic intervention did not cause any appreciable harm to the recipient, the benefits associated with the procedure were not easy to define in terms of graft survival. Quality of cells, quantity of cells, time of administration, and prolongation of chimeric status were all considered variables that supported the "feeling" of improved results, but did not offer any unquestionable and tangible parameters to quantify this sense of improvement (173-177).

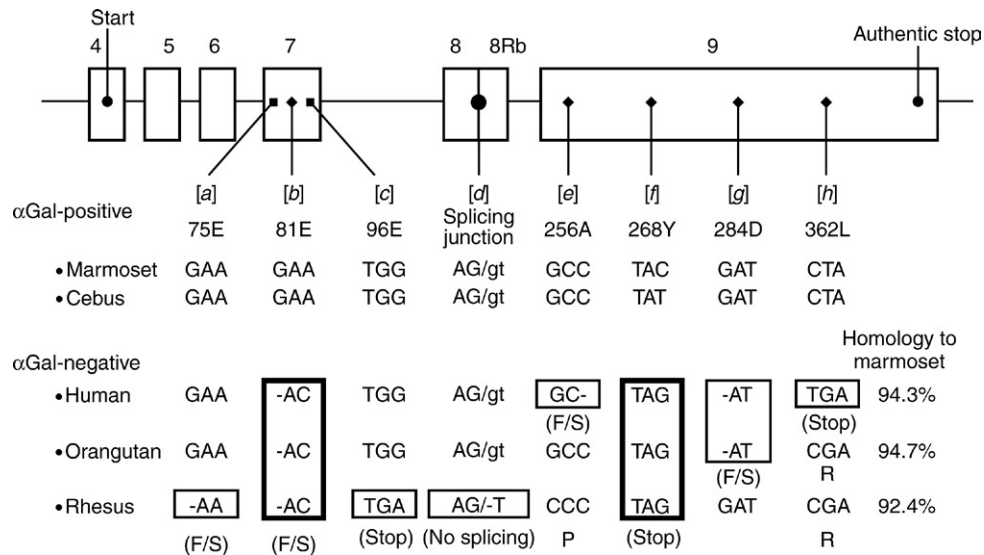

**FIGURE 40-14** Artistic representation of a chimera from Greek mythology and evidence of an immunologic chimera in a patient with Gaucher disease. In (A), Khimaira, also spelled in the Latin “Chimera,” was a powerful beast with the head of a male lion, the body of a goat, and, as a tail, a serpent. The legend states that she was slain by Bellerophon with a golden arrow, while he rode on the back of Pegasus, a horse with wings. The Chimera of Arezzo is conserved at the Archaeologic Museum in Florence, Italy. In (B), genomic DNA was extracted from the recipient’s tissues and amplified with HLA-DR beta-chain “generic” oligonucleotide primers to determine the subgroup of the donor’s alleles. “Specific” primers were then used to amplify the alleles selectively. The alleles were identified by hybridizing the amplified DNA to radiolabeled allele-specific probes. HLA-DR1 was only present in the donor. After HLA-DR1–specific amplification of DNA from the liver (L), blood (B), bone marrow (BM), skin (S), and small bowel (SB) of the recipient, the DNA was separated by electrophoresis on an agarose gel and then analyzed by Southern blotting. The denatured DNA present on the nylon membrane was hybridized to a labeled HLA-DR1 (donor)-specific oligonucleotide probe. For liver DNA, the quantity analyzed was reduced to 1% of the other samples. Although lower in intensity, the signal from donor DNA in the small bowel was clearly positive in the original film, although this can be seen here only faintly. The negative control was a reaction run without DNA (last lane; N = negative control). (From Starzl, T. E.; Demetris, A. J.; Trucco, M., et al. *Chimerism After Liver Transplantation for Type IV Glycogen Storage Disease and Type I Gaucher’s Disease*. N. Engl. J. Med. 1993; 328, 745–749.)

#### 40.10 GENETICS OF XENOTRANSPLANTATION

A more drastic but also theoretically valid alternative is the one originally proposed by David Sachs et al. (178,179) that considered the radiologic ablation of the recipient bone marrow followed by the transplant of mature-T-cell-free mixture of recipient and donor bone marrow cells. In the mouse, the simultaneous presence of the two immunologic systems, even from individuals with different histocompatibility phenotypes, allows the immunologic reconstitution of the recipient by both types of cells together. The established chimerism is, in this case, quite stronger in percentage of donor versus recipient cells than the one obtainable by bone marrow augmentation. Once proved durable, this chimerism is able to allow the acceptance of any organ coming from the same donor. More recently, autoimmune diabetes in the NOD mouse model can be treated with bone marrow from autoimmunity-free allogeneic donors (180) and that restoration of endogenous  $\beta$ -cell function to physiologically sufficient levels is achievable even if the

allogeneic BMT is performed after the clinical onset of diabetes (181).

The establishment of an immunologic chimerism has even been proposed to set the basis for possible xenotransplantation (178). An immediately available, unlimited source of tissues may be found in animals, and the pig seems to be the animal of choice because of its size and its already established, regulated, massive production for alimentary use (182). This possibility could not be further explored when it became clear that the  $\alpha$ 1,3 galactose ( $\alpha$ 1,3-Gal) epitopes on pig tissues were the targets of antibodies, normally present in the human serum, able to quickly reject the xenotransplant (183). Humans do not express a functional  $\alpha$ 1,3-galactosyltransferase ( $\alpha$ 1,3-GT) gene and, as a consequence, their tissues are  $\alpha$ 1,3-Gal-negative. However, it is likely that  $\alpha$ 1,3-Gal-positive microbial colonies within the human gastrointestinal tract result in immunological exposure to the antigen. As a result, humans develop antibodies against the antigen before xenograft exposure and promptly reject antigen-positive tissue. The only notable exception is Old World monkeys, which, similar to humans, are  $\alpha$ 1,3-Gal-negative. These antibodies are able to mount a rapid, deleterious reaction that is the major cause of xenograft loss in the first few hours after transplantation. This is now known as “hyperacute rejection.” To avoid the HAR of the tissues from  $\alpha$ 1,3-Gal-positive pigs, we considered the possibility of generating pigs genetically deprived of the activity of the enzyme  $\alpha$ 1,3-GT and, consequently, free of  $\alpha$ 1,3-Gal epitopes at their cell surface. Toward this end, we began cloning the  $\alpha$ 1,3-GT gene of the pig, together with its regulatory 5′ sequence. The cloning and sequencing of a stretch of genomic DNA ~30,000 nucleotides long, encompassing a regulatory sequence containing the gene promoter, 9 exons, and relative introns, was successfully completed at the end of the year 2000 (184). Then, it was our view that the best way to inactivate, in the pig, both alleles of the  $\alpha$ 1,3-GT gene, without creating lethal conditions for the pig embryo, could be determined by properly defining and evaluating the molecular reasons why the same gene is not functional in humans. Our comparison between human, orangutan, and rhesus (all  $\alpha$ 1,3-Gal-negative species) alternatively spliced  $\alpha$ 1,3-GT mRNAs, and marmoset and cebus ( $\alpha$ 1,3-Gal-positive species) normally translated  $\alpha$ 1,3-GT sequences, revealed a site, at the beginning of exon 9 of the gene, as possibly the most critical point for the enzyme proper function. A stop codon, TAG, substituted the amino acid at position 268 of the functioning enzyme (Figure 40-15) causing the production of a truncated protein, and the complete abrogation of the enzyme function (185). We began a close collaboration with the Virginia branch of Scottish PPL Therapeutics Inc., which had experts in the genetic modification of livestock and the application of homologous

**FIGURE 40-15** Comparison of crucial point mutations of the  $\alpha 1,3$  GT gene in primates. (From Koike, C.; Fung, J. J.; Geller, D. A., et al. *Molecular Basis of Evolutionary Loss of the  $\alpha 1,3$ -Galactosyltransferase Gene in Higher Primates*. J. Biol. Chem. 2002, 277, 10114–10120.)

recombination, gene targeting, and animal cloning (i.e. somatic cell nuclear transfer). As such, PPL Therapeutics was responsible for cloning the first mammal, “Dolly” the sheep. In addition, in March 2000, PPL Therapeutics generated the world’s first cloned pigs (186). Thus, genomic sequences encompassing the beginning of exon 9 were used to construct knockout (KO) vectors aimed at the targeted insertion of a selectable marker gene (e.g. neo), and at the inactivation of the  $\alpha 1,3$ -GT gene in pig fetal fibroblast cells. Cells carrying the  $\alpha 1,3$ -GT gene KO were then isolated and used as donors for somatic cell nuclear transfer (cloning) to produce a single  $\alpha 1,3$ -GT gene KO pigs (187). To produce animals useful for transplantation, it was necessary, however, to knockout also the second, yet noncompromised allele of the gene that was responsible for the still present expression of  $\alpha 1,3$ -Gal epitopes on the single KO pig cells. To knockout the second allele, then, an effective selection technique for the isolation of  $\alpha 1,3$ -Gal-negative fibroblasts was developed: the toxin A of *Clostridium difficile* uses the  $\alpha 1,3$ -Gal epitope as the receptor to get into the target cells, thus selectively killing  $\alpha 1,3$ -Gal-positive cells. After toxin A treatment, the surviving fibroblasts still carried the first KO allele of the  $\alpha 1,3$ -GT gene but also had the second allele of the  $\alpha 1,3$ -GT gene inactivated. When the second  $\alpha 1,3$ -GT gene allele was sequenced, we found a “T–G” transversion in the second base pair of exon 9 in its coding region, which caused a single amino acid change, from tyrosine (Tyr) to aspartic acid (Asp), in the  $\alpha 1,3$ -GT protein (Figure 40-16). This change is precisely located in the active site of the enzyme and totally impairs its function (188). These cells deprived of  $\alpha 1,3$ -GT activity were then used for nuclear transfer to produce the first  $\alpha 1,3$ -GT double knockout (DKO)

**FIGURE 40-16** Sequencing analysis of  $\alpha 1,3$  Gal-positive and  $\alpha 1,3$  Gal-negative alleles in the cloned pigs. (From Phelps, C. J.; Koike, C.; Vaught, T. D., et al. *Production of  $\alpha 1,3$ -Galactosyltransferase Deficient Pigs*. Science 2003, 299, 411–414.)

cloned pigs. “DKO” was a preferred definition because our pigs were not actually “homozygous” for the same KO allele. On the basis of immunohistochemistry, histologic staining of pig tissues, and immunoreactivity tests (Figure 40-17), it was shown that the cells of the newly generated DKO pigs did not express any  $\alpha 1,3$ -Gal epitopes at their surface (188).

Even without the  $\alpha 1,3$ -Gal epitopes, the tissues from the DKO pigs needed a strong immunosuppressive regimen for acceptance into a nonhuman primate recipient. The generation of an immunologic chimerism between these two species might be the only way to allow this type of xenotransplantation. Xenotransplantation can become a reliable treatment when new strategies are developed that overcome the immunologic hurdles and avoid the use of intensive immunosuppression. However, the risks involved in lethally treating the recipient have

**FIGURE 40-17** Anti- $\alpha$ 1,3-Gal IgM production in  $\alpha$ 1,3-Gal-negative mice (208) injected intraperitoneally (i.p.) with DKO or wild-type (WT) tissues. The tissue from the DKO piglet failed to generate any increase in anti- $\alpha$ 1,3-Gal IgM in the recipient  $\alpha$ 1,3-Gal-negative mice, whereas tissue from neonate wild-type piglets, used as a control, generated significant increases in the IgM titer, demonstrating, in vivo, that tissues from DKO pigs lack any immunogenic  $\alpha$ 1,3-Gal residue at their surface. (From Phelps, C. J.; Koike, C.; Vaught, T. D. *et al. Production of  $\alpha$ 1,3-Galactosyltransferase Deficient Pigs. Science* 2003, 299, 411–414.)

so far precluded any application of this type of protocol in humans but may constitute a very valuable tool for future improved applications. Along this line of reasoning, van der Windt *et al.* (189) reported long-term control of blood sugar in streptozotocin treated diabetic non-human primates, showing that expression of the human complement regulatory protein (hCD46) on pig islets improved the length of time in which recipient animals were normoglycemic. For example, four of five recipient animals exhibited graft survival and insulin independent normoglycemia for 3 months (end of experiment) and one recipient, selected at random, was normoglycemic for greater than 1 year post-transplantation (189).

## 40.11 STEM CELLS AND TRANSPLANTATION

Although all these approaches are designed to bypass the limitations imposed by different genetic profiles, a rather new and somewhat revolutionary alternative has recently been offered: Stem cells can be derived from the embryo or found in different tissues of an individual and are able to replace differentiated cells of different organs.

A stem cell is, by definition, the cell capable of duplicating itself and resuming its undifferentiated status, while also originating progeny that can differentiate into one or more final products that are physiologically defined by their specific functions (190). Proceeding through the differentiation pathway, stem cells can be categorized as totipotent, pluripotent, multipotent, oligopotent, and unipotent, depending on all their possibly reversible, progressively acquired characteristics (191). Embryonic stem (ES) cells are pluripotent cell lines derived from the inner cell mass of blastocyst-stage embryos. ES cells differentiating in culture may reproduce features characteristic of

early embryonic development. The ability to clone human embryos and to derive from them human ES cell lines is already a reality (192–195). Even imagining that tomorrow’s scientists could derive, by cloning, cell lines able to be differentiated toward cells with a desired phenotype and in sufficient number to satisfy the needs of the transplant recipient, to use them for clinical purposes, they should be carrying the diploid genome of somatic cell nuclei derived from individuals unrelated to the oocyte donor (i.e. the recipients). Even so, we would still need to isolate the broadest diversity of HLA polymorphisms, to more easily find a match between donor and recipient so to avoid the serious problem of allojection. In the case in which we opt to avoid all this demanding preparative effort for matching donor and recipient, it would be necessary to reduce the likelihood of allojection by other means (190). However, in the case of ES cells, it may be easier to achieve this goal because the already studied human ES cell lines seem to be able to down-regulate the expression of MHC antigens at their surface (196,197). Rapidly dividing cells with this unique phenotype have to spontaneously stop growing once a specific, predetermined, total population cell mass has been reached as they seem not even normally controlled by NK cells (196). In the case in which the ES cells do not stop proliferating, we will transplant cancer precursors into our patients. Furthermore, even assuming that we could overcome all these challenges, the use of human ES cell lines tailored ad personam would constitute an extremely demanding and expensive proposition (198). If ethical considerations will not block this type of experimentation, the stem cell avenue seems to be the most promising and exciting avenue for autologous, as well as allogeneic, transplantations.

More ethically acceptable certainly is the use of so-called “adult” stem cells, that is, precursor cells present in the tissue of already completely formed individuals. Years ago, Mulligan *et al.* (199) were able to show how stem cells isolated from the bone marrow were able to replace malfunctioning myocytes in a mouse model of Duchenne muscular dystrophy. This approach envisions isolating in vitro adult pluripotent stem cells from any manageable source (e.g. the bone marrow) and physically introducing these cells into the already existing, appropriate environment of living recipients. This assumes that the signals sent via host-secreted factors or by cell-to-cell contacts are powerful enough to guide the transplanted precursors to differentiate into the same type of cells surrounding them, even across different lineages. By receiving spatially and temporally restricted signals from the environment, the precursors may differentiate into the cells constitutive of that specific, target tissue. Using a cocktail of specific antibodies able to recognize a combination of distinct cell surface markers (c-kit<sup>high</sup>Thy<sup>low</sup>Lin<sup>+</sup>Sca-1<sup>+</sup>) on a single cell, Lagasse *et al.* (200) physically isolated HSCs from bone marrow and transplanted them into the fumarylacetoacetate-hydrolase-deficient mouse, an

animal model of fatal hereditary tyrosinemia type I. Four out of nine mutant mice had near-normal liver function (transaminase and tyrosine levels were slightly increased) when, three weeks after transplantation, the standard treatment with 2-(2-nitro-4-trifluoro-methylbenzyl)-1,3-cyclohexane-dione was discontinued. These mice survived for an additional 6 months without signs of progressive liver failure or renal tubular damage. When the experiment, at 7 months after transplantation, was interrupted, 30–50% of the liver mass showed cells expressing donor-derived markers. Similarly, by transferring precursors into the brain of a recipient mouse, Weimann et al. (201) were able to see purified HSCs differentiate into Purkinje neurons. Similar to HSCs, once transduced with a retrovirus to express bone morphogenetic protein 4 (BMP4), muscle-derived cell precursors were able to dramatically improve the healing of a spontaneously irreparable bone fracture (202). Taken together, these research reports suggest an abundance of promising opportunities for BMT in the treatment of chronic diseases. However, for the moment, the only tested clinical exploitation of adult stem cells is the one taking advantage of CD34<sup>+</sup> cells of the bone marrow.

In the most recent years, different groups established that 1–3% of cells in the bone marrow are capable of long-term multilineage hematopoietic reconstitution after myeloablation (203). These cells can be mobilized from the marrow to the peripheral circulation in clinically usable numbers, by the use of recombinant hematopoietic cytokines, similar to the granulocyte colony-stimulating factor. Once mobilized, these cells can be isolated from the peripheral blood by cell sorting using anti-CD34 antibodies. CD34<sup>+</sup> cells isolated from the peripheral blood have a number of advantages when compared with whole bone marrow for transplantation: they are potentially less tumor-contaminated than autologous marrow when used for autologous transplantation; their time for engraftment is shorter; the isolated CD34<sup>+</sup> cells are more amenable to *ex vivo* manipulations such as gene therapy; and even when used in the allogeneic setting, they eliminate acute GVHD and significantly reduced the incidence and severity of chronic GVHD. Unfortunately, these advantages are counterbalanced by the missing positive roles played by graft T-cells able to facilitate engraftment, eliminate residual leukemic cells, and transfer of donor immune memory (204).

In 2006, the creation of induced pluripotent stem (iPS) cells was described (205). Derived from mouse adult somatic cells by the ectopic expression of the transcription factors Oct3/4 (Pou5f1), Sox2, Klf4, and c-Myc, using viral as well as plasmid-based vectors has been shown to be sufficient to direct the reprogramming of adult somatic cells. During the following year, iPS cells were generated from human somatic cells (206) as a result of the combined expression of Oct3/4, Sox2, Klf4, c-Myc and independently with the expression of Oct3/4, Soc2, Nanog, and Lin28. The importance of iPS cells to

transplantation medicine occurs as a result of the cells being derived entirely from the recipient. Thus, these cells bypass transplantation complications such as GVHD and immune rejection. A recognized danger associated with the method for preparing iPS cells is the risk of inducing the expression of oncogenes, such as c-Myc, as well as the possible incorporation of transcription factors into unfavorable sites within the genomic DNA with the potential to induce coexpression of neighboring oncogenes. In 2009, Jaenisch et al. (207) reported the development of protocols for removing oncogenes after the induction of pluripotency, providing a possible solution to this complication. Moreover, it was reported in 2009 that iPS cells could be induced without alteration of genomic DNA (208). This was accomplished by repeated treatment with proteins Oct3/4, Sox2, Klf4, and c-Myc modified with polyarginine anchors to generate what has been termed protein-induced pluripotent stem cells (piPSCs). In the not-too-distant future, the use of iPS cells may circumvent the problem of stem-derived cell allotransplants (e.g. limiting material and immune-mediated rejection) making them equivalent to autotransplants, while also minimizing the risk of exposing the recipient to an uncontrolled neoplastic transformation of the cells.

## 40.12 CONCLUSION

The data presented clearly show that HLA matching does not and cannot influence solid organ distribution significantly. However, these analyses support the wisdom of the UNOS Board of Directors to mandate national sharing of the zero serologically mismatched HLA cadaveric donor kidneys in the rare cases where they occur. HLA matching for other solid organ grafts is even more problematic because the patients needing livers or thoracic organs are generally critically ill and cannot tolerate extensive waiting periods. The recent success in transplanting a single lobe of the organ from alive or cadaveric donors into one or more recipients, respectively, may expand these limited chances. On average, only about 30% of candidates for BMT will have an HLA-identical sibling or other suitable related donor. Leukemia is the most common diagnosis of BMT potential recipients. Survival and cure rates for acute nonlymphocytic leukemias are almost as great after autologous BMT as for HLA-identical sibling BMT. This is not the case for acute lymphocytic leukemia patients, however. Unfortunately, those patients with uncommon HLA phenotypes will not survive a lengthy search for an unrelated donor. At the present time, few chronic lymphocytic leukemias are considered candidates for bone marrow transplant; therefore, the NMDP and other registries of unrelated donors benefit primarily patients with chronic myelogenous leukemia. Thus far, the outcome of unrelated transplants for chronic myelogenous leukemia has been poor because of HLA mismatching not detected by serologic and cellular assays. It is anticipated that improvement will be seen

now that typing by DNA-based methods for class II are in place. Once this is accomplished, the next major effort for the future will be to identify which minor differences between variants can be tolerated with little or no risk of rejection or GVHD, or which tolerogenic protocol can offer safe but effective means to allow transplants across HLA boundaries or even across different species without the need for massive immunosuppression.

## Biographies

**Gaia Bellone** is a graduate student in the Department of Statistics at Carnegie Mellon University. She graduated in Economics from Bocconi University, Italy (BA 2005) and obtained her master degree in Statistics from Carnegie Mellon University (2008). She worked as Financial Analyst at a privately held financial institution. Her research focuses on the development of advanced statistical methods for analyzing sequencing data.

**Massimo Trucco** graduated summa cum laude in Medicine at the University of Turin, Italy, in 1974. In 1977, as assistant professor of Medical Genetics, was visiting the MRC laboratories in Cambridge, UK, working with Cesar Milstein; then moved to the Basel Institute of Immunology, Switzerland, directed by Niels Jerne. Here, Trucco published the characterization of the first anti-HLA monoclonal antibodies (*Nature* 273:666, 1978). In 1981, Trucco was at the Wistar Institute, University of Pennsylvania, where studied the molecular basis of HLA-DQB1 histocompatibility alleles (*Nature* 309:166, 1984). In 1986, Trucco moved to the University of Pittsburgh, appointed as associate professor in Pediatrics. With Dr McDevitt, Stanford University, the HLA-DQB1 alleles were characterized as the most-sensitive markers for type 1 diabetes susceptibility (*PNAS* 85:8111, 1988; *PNAS* 87:7370, 1990). In 1990, Trucco, as the Head of the Division of Immunogenetics, cloned the NK1-1 encoding gene (*Science* 249:1298:1990). In 1991, received the Henry Hillman endowed chair as Professor of Pediatric Immunology. In 1996, Trucco received the University of Pittsburgh Chancellor's Distinguished Award for his work on diabetes (*Nature* 371:351, 1994; *Nature* 380:284, 1996). This constituted the basis for opening the new Diabetes Institute, of which he became, and still is, the first Scientific Director.

**Steven Ringquist** is a research assistant professor at the Children's Hospital of Pittsburgh. He received bachelor degrees in Chemistry and Biology from California State University (BA 1982) and a doctorate degree in Biological Chemistry from the University of Illinois (PhD 1987). He went on to study within the field of genomics at Columbia University (1988–1989) where he mapped epigenetic changes occurring in genomic DNA. Later he worked at the University of Colorado (1990–1993) on developing experimental and computational models for measuring the influence of RNA elements that control gene expression. Beginning in 1994 his work at a pharmaceutical company developing modulators of protein activity resulted in the awarding of nine U.S. Patents. He returned to academia by obtaining a fellowship at the Sidney Kimmel Cancer Center where he investigated changes in expression of low copy number mRNA from tumor cells (1998–2000). In 2001, he moved to his current position at the Children's Hospital of Pittsburgh. Ringquist's research combines genetic, proteomic, and computational tools for the identification of molecular markers that predict transplantation outcome as well as susceptibility to autoimmune disease.

**Ying Lu** is a researcher at the Children's Hospital of Pittsburgh. He graduated from NanKai University, China (BS 1995) and pursued postgraduate studies in the Department of Computer Science at Rensselaer Polytechnic Institute (MS 2002) and in the Department of Chemistry at the University of Pittsburgh (MS 2005). He worked as adjunct staff at Proteomics Core Lab at Pitt (2003–2004). He then joined Dr Trucco's laboratory in 2005. His research focuses on the use of genomics and proteomics to elucidate the molecular mechanisms underlying diseases of the immune system.

## The Genetics of Disorders Affecting the Premature Newborn

*Aaron Prosnitz*

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

*Jeffrey R Gruen*

### 41.1 INTRODUCTION

Premature birth, occurring prior to 37 weeks of gestation, affects more than 12% of births in the USA. The rate of premature birth has risen 35% since 1981 (1) and is the leading cause of infant morbidity and mortality, with an estimated annual economic cost of \$26 billion. Despite improvements in perinatal and neonatal care over the past four decades, outcomes have remained stagnant over the last 15 years (2).

Immaturity of the immune system and increased oxidative stresses (3) in the setting of an immature antioxidant system are common pathways that contribute to the morbidity and mortality of prematurely born infants. There is a delicate balance that exists between the creation of reactive oxygen species (ROS) and cellular antioxidant defenses, and that balance is particularly perturbed in the preterm infant, placing the child at increased risk for oxidative damage (4). The preterm infant is exposed to increased ROS through the processes of hyperoxia, reperfusion, and inflammation. In addition, the antioxidant defenses are immature in preterm infants. Both upregulation of endogenous production of antioxidant enzymes (AOE) and maternal–fetal transfer of AOE occur in the final 12% of gestation, in preparation for the transition to the relative hyperoxia of extra-uterine life. A lack of mature ROS defenses may increase the risk for developing bronchopulmonary dysplasia

(BPD), retinopathy of prematurity, and periventricular leukomalacia, which have been linked to oxygen radical species (4).

In addition to the contributions that the premature physiologic state makes to the pathogenesis of the disorders commonly seen in the premature infant, genetics also plays a strong role (5). Historically, prenatal and perinatal disorders were considered to be more purely genetic, since chromosomal abnormalities and single-gene recessive errors of metabolism are responsible for many spontaneous abortions, miscarriages, and perinatal deaths (see Figure 41-1A). However, contemporary studies in the neonatal period permit a new paradigm in which disorders of the premature infant can be considered as complex, multifactorial, and polygenic, and the result of gene–environment interactions. Between 21 and 38 weeks of gestation, genetic factors can be thought of as influencing the newborn's tolerance to the inherent stressors of prematurity and to the toxicities of life-saving interventions such as positive pressure ventilation, oxygen therapy, and enteral feedings (see Figure 41-1B). Genetic approaches to the diseases of the neonatal period that address the pathophysiology of prematurity as tolerance to gene–environment interactions, beyond just global immaturity, will allow investigators to take advantage of new genetic resources and technologies that have been developed over the past two decades.

**FIGURE 41-1** Continuity of disease across the lifetime. (A) Conventional depiction of genetic disease from conception to adulthood. (B) Recognition of complex diseases in the premature very-low-birth weight neonate born between 24 weeks and term. White peaks are chromosomal aberrations. Grey peaks are Mendelian single-gene disorders. Hatched peaks are complex disorders. (Reprinted with permission from Bhandari, V.; Gruen, J. R. *The Genetics of Bronchopulmonary Dysplasia*. Semin. Perinatol. 2006, 30, 185–191.)

In the sections below, we present the evidence for heritability and consider candidate gene studies for the six most common causes of neonatal morbidity in infants born less than or equal to 28 weeks and 1500 g (28% overall morbidity): respiratory distress syndrome, BPD, patent ductus arteriosus (PDA), intraventricular hemorrhage (IVH), retinopathy of prematurity, and necrotizing enterocolitis (NEC) (6).

## 41.2 RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is a condition that predominantly affects preterm infants. Formerly known

as hyaline membrane disease, RDS is caused by a lack of mature surfactant in the alveoli, resulting in higher than normal surface tension and thus decreased alveolar ventilation and atelectasis. The atelectasis causes ventilation-perfusion mismatching, hypoxia, and eventual respiratory failure. Infants are most at risk before 32 weeks of gestation, prior to the development of secondary septation/alveolarization that would result in a more mature lung (7).

RDS affects approximately 10% of all premature infants. Gestational age (GA) and birth weight (BW) are inversely proportional to the risk. It occurs in fewer than 5% of babies born after 34 weeks' gestation, in 30% of babies born between 28 and 34 weeks' gestation, and 60% of preterm infants born prior to 28 weeks' gestation (8).

Additional risk factors include male sex, white race, maternal gestational diabetes, perinatal asphyxia, hypothermia, and multiple gestations (9). Current treatment modalities have improved RDS mortality from nearly 100% to less than 10% (10), yet RDS is a leading cause of morbidity and mortality in preterm infants with an estimated annual economic cost of \$2.3 billion (8).

### 41.2.1 Twin Studies

Twin studies have suggested that genetic factors play an important role in determining susceptibility and severity. In 1996, Nagourney et al. (11) determined that second twin siblings had a significantly increased risk of RDS compared with the first twin, after controlling for confounding variables. In 1971, Myrianthopoulous et al. studied 31 twin pairs and showed a higher concordance between monozygotic (MZ) pairs compared to dizygotic (DZ) pairs (85% versus 44%, respectively) (12). Similarly, a retrospective study of 194 preterm (GA 30–34 weeks) twin pairs in the Netherlands found that RDS occurred more frequently in both twins when the twins were MZ (67% versus 29%,  $p < 0.05$ ) (13). While the study from the Netherlands suggested a strong genetic influence, it only included 80 pairs with a GA of 30–34 weeks, which is a GA of relatively low risk for developing RDS.

In contrast, Marttila et al. investigated 100 same-sex twins with RDS and found a concordance difference of only 10% (95% confidence interval (CI)  $-0.1$  to  $+0.3$ ,  $p = 0.32$ ) (14). In a follow-up study, the same group evaluated the concordance between same-sex and opposite-sex RDS rates within a collection of 23,278 twins from Europe (15). The authors found no difference in concordance between the two groups and concluded that environmental factors predominated over genetic factors. Both of these studies, however, lacked a formal determination of zygosity. In addition, several studies have shown the importance of sex in frequency and severity of RDS, calling into question the validity of these studies that were based on sex.

### 41.2.2 Heritability of RDS

Levit et al. performed a multicenter retrospective study of 332 twin pairs less than 32 weeks GA, and computed the heritability of RDS. Using placental pathology and sex concordance for determining zygosity, and after correcting for major known environmental risk factors, they found the heritability to be 49.7% ( $p = 0.04$ ) (16). Taken together, the twin and heritability studies suggest that genetic factors account for a significant proportion of the variance for RDS.

### 41.2.3 Candidate Genes

Candidate gene studies of surfactant proteins have shown evidence for genetic associations (see Table 41-1).

Surfactant is composed of a mixture of phospholipids (mainly phosphatidylcholine) and surfactant proteins (SPs) A, B, C, and D (64). SP-A regulates secretion and uptake of surfactant and plays a role in innate host defense, while SP-B and SP-C assist in adsorption and spreading of the phospholipid monolayer along the surface of the alveolus (65). SP-D is thought to participate in surfactant reuptake and recycling (66). Several studies have found associations between SP polymorphisms and the risk for developing RDS, particularly involving *SP-A* and *SP-B* alleles, reviewed by Hallman and Haataja (67).

### 41.2.4 *SP-A* and *SP-B* Studies from Finland

There have been five studies of RDS in prematurely born infants from Finland. Marttila et al. (50), in their study of 198 premature twin pairs, noted the *SP-A1* allele 6A2 ( $p = 0.030$ ), genotype 6A2/6A2 ( $p = 0.0042$ ), and haplotype 6A2-1A0 ( $p = 0.016$ ) were overrepresented in healthy premature twins when compared with twins with RDS. In healthy twin pairs, the genotype 6A2/6A2 was overrepresented, compared with concordant RDS twins (odds ratio (OR) 0.18, 95% CI 0.06–0.60,  $p = 0.0016$ ). A larger study by the same group collected data on 441 singletons and 480 multiples from Finland (51). Contrary to the prior study of twins, both the *SP-A1* allele 6A2 and the homozygous genotype 6A2/6A2 were overrepresented in small RDS singletons when the *SP-B* exon 4 genotype was Thr131/Thr131 ( $p = 0.009$  and  $p = 0.003$ , respectively). This combination of 6A2 and Thr131 was associated with a fourfold increase in risk. However, 6A2 alleles were underrepresented in RDS of near-term multiples when the *SP-B* genotype was either Ile/Thr ( $p = 0.012$  and  $p = 0.003$ , respectively) or Thr/Thr ( $p = 0.12$  and  $p = 0.018$ , respectively). In this study, the *SP-A* 6A2 allele with the *SP-B* Thr131 allele was detrimental to singleton infants but protective to multiples.

Ramet et al. showed that within a cohort of 176 Finnish preterm infants, the *SP-A1* allele 6A2 was more prevalent in infants with RDS (allelic frequency 0.65 versus 0.52,  $p = 0.017$ ), while the 6A3 allele frequency was less frequent in the RDS group (0.24 versus 0.34,  $p = 0.034$ ). The authors did not find any significant association between *SP-A2* alleles and RDS (52). A companion study by the same group investigated 684 premature infants, 184 with RDS, showing that the *SP-B* Ile131Thr genotype modulated the effect of the various *SP-A* alleles on RDS risk (increased with 6A2 and 1A0, decreased with 6A3 and 1A2) (53). In a later transmission disequilibrium study of 107 white parent-offspring trios from Finland, Haataja et al. showed that the *SP-A1-A2* haplotype 6A2-1A0 increased, and *SP-A1* 6A3-1A1 6A4-1A5 genotypes decreased the risk for developing RDS (56).

### 41.2.5 *SP-A* and *SP-B* in Preterm Infants from Germany

In an unrelated study of *SP-B* polymorphisms, Makri et al. looked at the rates of RDS among 140 white preterm infants from Germany (59). Among other findings, those infants carrying non-wild-type polymorphisms in *SP-B* intron 4 (either deletions or insertions) were found to have a significantly increased risk of developing RDS (93.1% versus 75.7%,  $p < 0.05$ ). Lyra et al. (58) also evaluated polymorphisms of *SP-B* in a cohort of 50 preterm infants with RDS and 100 healthy term infants. When only the white children were compared, there was a statistically significant difference in the RDS and control groups in the G(8714)C polymorphism rate ( $p = 0.028$ ).

### 41.2.6 Racial Differences

Studies by Kala and Floros showed a difference in risk factors conferred by *SP* genotypes between black and white subjects. In a study of 241 infants greater than 28 weeks GA, Kala et al. (54) found an overrepresentation of 1A0, 6A2, and 6A4 alleles in the RDS white subjects, whereas 1A1, 1A2, and 6A3 were significantly more frequent in the RDS black subjects. In addition, *SP-A2* 1A0/1A0 was found more frequently ( $p = 0.035$ ), and *SP-A2* 1A1 was found less frequently ( $p = 0.005$ ) in a subgroup of 82 white infants greater than 28 weeks GA with RDS compared with 83 controls. Synergistic positive association with RDS was also observed in white infants greater than 28 weeks GA when the 1A0 allele was present concurrently with a previously described *SP-B* intron

4 polymorphic variant. Floros et al. (55) investigated a group of 511 white and 72 black preterm infants and the interactions between *SP-A* and *SP-B* alleles in conferring RDS risks, in order to further understand the increased risks seen among white infants. They found that the *SP-A* 16A2/6A2 genotype and the *SP-A* 1A0/1A0 or 1A0/\* genotype were associated with an increased risk in the white population when the *SP-B* genotype was A(9306) G or (del/\*). The *SP-A* 16A3/6A3 and 6A3/\* genotypes, in the setting of *SP-B* genotype 1580(T/T), conferred reduced risk in the black population. In a similar fashion, an *SP-B* intron 4 insertion variant conferred increased risk to black females, while the *SP-B* intron 4 deletion variant conferred an increased risk in white males.

The efficacy of single nucleotide polymorphism (SNP)-based studies for identifying clinically significant polymorphisms for *SP-B* has been called into question. Hamvas et al. (68) evaluated the genomic stability of the *SP-B* gene, and showed excess low-frequency variation, intragenic recombination, and lack of common disruptive exonic variants. They concluded that SNP-based and linkage disequilibrium studies of the *SP-B* gene in diverse populations should involve complete resequencing.

#### 41.2.7 *SP-C* and RDS

Dominant mutations of the *SP-C* gene are known to be associated with interstitial lung disease. Lahti et al. (69) tested whether non-dominant *SP-C* alleles 138Asn (exon 4) or 186Asn (exon 5) could also affect the risk for RDS, after adjusting for sex. In a cohort of 245 preterm infants from Finland, both alleles were found to be independent risk factors for RDS (138Asn: OR 2.01, 95% CI 1.10–3.66,  $p=0.022$ ; 186Asn: OR 1.87, 95% CI 1.04–3.38,  $p=0.036$ ). They showed similar results for the haplotype 138Asn-18Asn (OR 2.05, 95% CI 1.12–3.74,  $p=0.020$ ). Of note, the associations for both alleles were observed to be stronger among male infants ( $p=0.018$  and  $p=0.045$ , respectively). Wambach et al. (70) investigated the complete *SP-C* gene sequences of 269 case-control white infants less than 34 weeks of gestation and identified 80 SNPs. They identified three SNPs within the promoter region as statistically associated with RDS: genomic position 1167 (OR 4.14, 95% CI 1.26–13.57,  $p=0.019$ ), genomic position 1647 (OR 12.75, 95% CI 1.58–103.15,  $p=0.017$ ), and genomic position 2385 (OR 13.0, 95% CI 1.60–105.09,  $p=0.016$ ).

#### 41.2.8 *SP-D* and RDS

There have been few studies of *SP-D* gene polymorphisms in the setting of RDS. Hilgendorff et al. (71) tested *SP-D* gene SNPs previously associated with adult pulmonary inflammatory disease. In a cohort of 284 premature infants, homozygote minor allele for SNP rs1923537 was associated with a lower prevalence of RDS (OR 1.733, 95% CI 1.139–2.636, adjusted  $p=0.0408$ ), lower number of total surfactant doses, less use of diuretics,

and a lower oxygen requirement at day 28 of life (71). In a haplotype transmission disequilibrium study of 132 families, Thomas et al. discovered that the two-marker *SP-D/SP-A* haplotype DA160 A/*SP-A* 1A1 reduced the risk of RDS ( $X^2=4.45$ ,  $p=0.035$ ) (72).

#### 41.2.9 Genes Related to Inflammation and RDS

The pathogenesis of RDS includes a significant inflammatory component. Capasso et al. (43) investigated known polymorphisms of inflammatory cytokines IL-8, IL-10, and TNF- $\alpha$  in 342 white newborns from Italy, 66 were prematurely born and had RDS. They found that the risk of RDS was significantly lower in preterm infants with the IL-10 genotype 1082 GG/GA than in those with the AA genotype (OR 0.48, 95% CI 0.24–0.95,  $p=0.03$ ). Further quantitative real-time polymerase chain reaction (RT-PCR) analysis demonstrated that IL-10 levels were higher in the GG/GA carriers ( $p=0.03$ ). A study by Bokodi et al. found that carriers of the cytokine allele IFN- $\gamma$  T(+874) A were at fourfold higher risk for developing RDS (OR 4.03, 95% CI 1.30–12.50,  $p=0.016$ ) (73). Additional work by this group found that a genotype associated with impaired heat shock protein cellular defense *HSP-72*(1267)GG genotype was associated with RDS (74).

#### 41.2.10 Meta-analysis

Treszl et al. (75) used a random forest technique to reanalyze previously published data of 24 SNPs among 135 preterm infants. Using relative importance scores (IS), they demonstrated that when including SNP information for E-selectin(128)Arg, TLR-4(399)Ile, IL-12 p40 CG, IL-18(-137)C, TNF- $\alpha$ (-238)A, IL-18(-607)A, *VEGF*(+405)G, and P-selectin(715)Pro (all IS > 1.2,  $p>0.1$ ), the accuracy of predicting the occurrence of RDS rose incrementally when compared to a baseline prediction utilizing only birth history data (0.72–0.77).

#### 41.2.11 Miscellaneous Genes and RDS

Other genes, in addition to *SP* genes, have been found to contribute to the development of RDS. *ABCA3*, an ATP-binding protein localized to the lamellar bodies of type II cells, is known to play a role in surfactant metabolism. *ABCA3* deficiency has been associated with cases of fatal RDS in full term infants (76). Karjalainen et al. found an association of the F353F allele in the *ABCA3* gene with a prolonged course of RDS in very premature infants (77). In an effort to study whether G-protein-coupled receptor for asthma susceptibility (GPRA) played a role in the pathogenesis of RDS, Pulkkinen et al. (78) performed a case-control study of 521 infants from Finland. They found that in preterm infants with RDS, the *GPRA* haplotype H1 was underrepresented in RDS, while the haplotype H4/H5 was associated with increased risk.

### 41.2.12 Summary of RDS

The genetic basis of RDS has been investigated by numerous twin studies, although concordance between twins was variable and could not uniformly determine the difference between familial and genetic factors. However, a multicenter study of 332 twin pairs with zygosity data showed that the heritability of RDS was 49.7%. To identify candidate genes associated with RDS, multiple investigators have studied the common polymorphisms of the four major surfactant protein genes (*SP-A*, *-B*, *-C* and *-D*) in cohorts of different sizes and demographics. The results from these studies were variable and often contradictory. Further studies of alternative candidate genes have been limited to six genes involved in either surfactant metabolism (*ABCA3*, *GPRA*) or the inflammatory cascade (*IL-8*, *IL-10*, *TNF- $\alpha$*  and *IFN- $\gamma$* ), without any independent validation. Meta-analysis of previously published polymorphism data suggests that genotypes may be incrementally helpful in determining the risk for developing RDS, but more systematic work on larger cohorts will be necessary to develop more robust and reproducible data.

## 41.3 BRONCHOPULMONARY DYSPLASIA

BPD is the most common chronic lung disease in infancy. It results from injury to the immature lung due to baro/volutrauma, exposure to hyperoxia, and in utero respiratory or systemic infections (79,80). Pathologically, BPD is defined as uniform inflation of the lung with impaired alveolarization, dysregulated vasculature, minimal airway metaplasia, smooth muscle hypertrophy, and fibrosis (81,82).

The diagnostic criterion for BPD is the requirement for supplemental oxygen at 36 weeks post-menstrual age (PMA) (79,82). It remains the most severe complication of preterm birth, affecting up to 23% of all infants with BWs between 500 and 1500 g (83). Demographic factors associated with BPD include GA, BW, male sex, white race, family history of asthma, and impaired growth for GA. During the perinatal period, low Apgar scores, asphyxia, PDA, pulmonary edema, duration of oxygen therapy, and various nutritional and mechanical ventilatory measures can also be associated with a higher risk (84). Prenatal maternal treatment with glucocorticoids decreases the risk. Long-term sequelae include general neurodevelopmental and quality of life impairments, increased risk of postnatal mortality, asthma, emphysema, pulmonary hypertension, systemic hypertension, and growth failure (84).

### 41.3.1 Heritability of BPD

There have been several studies that used multiple births to assess heritability. Parker et al. (85) were the first to

compare concordance among 108 very low birth weight (VLBW) twins. BPD status in one twin significantly predicted the risk in the other twin (adjusted OR 12.3,  $p < 0.001$ ) when adjusted for BW, GA, sex, RDS, pneumothorax, PDA, birth order, and Apgar scores. Bhandari et al. compared concordance in 450 twin pairs (86) and showed that 65.2% (95% CI 52.6–78.9%,  $p < 0.001$ ) of the variance could be accounted for by a combination of shared genetic plus environmental factors, after controlling for male sex, BW, and RDS. Zygosity data in a subgroup of subjects allowed for quantification of heritability through a comparison of MZ and DZ twins. After controlling for covariates, the heritability of BPD was 53% (95% CI 16–89%,  $p = 0.004$ ). A later study by Lavoie et al. (87) showed a higher heritability (>79%) after differentiating mild from more severe forms. In this study, mild BPD (oxygen dependence at 28 days of life), which usually resolves over time, was primarily attributable to shared environmental effects. Moderate to severe BPD (oxygen dependence at 36 weeks PMA), however, was attributable to primarily genetic factors. This suggests that genetic association studies should be stratified for severity or should only include subjects with moderate to severe disease.

### 41.3.2 Candidate Genes

BPD can be viewed as a disease of gene–environment interactions, rather than the traditional view of interrupted development. More recent studies have begun to test the large number of candidate genes that participate in the process of lung development, inflammatory regulation, oxygen toxicity, cell injury, tissue repair, surfactant production, and sepsis. These studies remain small and poorly replicated, but they highlight the shift from developmental to genetic factors in the investigation of this critical disease process.

### 41.3.3 Surfactant Genes and BPD

While surfactant proteins are frequently studied in relation to the pathogenesis of RDS (as described above), studies have shown an association with BPD as well. In a small study of 23 GA-matched preterm infants with BPD, Weber et al. (57) found that the *SP-A1* 6A6 allele was significantly overrepresented in the BPD group, suggesting that *SP-A* polymorphisms are an independent risk factor. Makri et al. (59) investigated the association between *SP-B* and BPD in a study of 140 preterm infants. The rate of BPD (using the older definition of requirement for supplemental oxygen on postnatal day 28) among infants with *SP-B* intron 4 deletion (*i4del*) was higher (21.6% versus 48.3%,  $p < 0.01$ ); however, the significance dropped out when the definition of BPD was extended to requirement for supplemental oxygen at 36 weeks PMA. A study of 140 preterm infants from Germany found similar associations between *SP-B* *i4del*

and BPD (60), particularly for the presenting twin. The intron 4 region of *SP-B* contains transcription factor binding sites that may allow for increased gene expression in response to infection or injury (88). A Finnish data mining study by Rova et al. (61) reported that the frequency of *SP-B* i4del, which may affect mRNA splicing and protein expression (89), was increased in 67 infants with BPD compared with 178 controls (OR 2.0, 95% CI 1.2–3.4,  $p=0.008$ ) (61). Pavlovic et al. found several associations with microsatellite markers from *SP-A*, *-B*, *-C*, and *-D* in 71 infants with mild or moderate BPD (90).

As described above, *ABCA3* is a protein involved in the storage and secretion of surfactant. Karjalainen et al. showed association of the *ABCA3* F353F allele with a prolonged course of RDS (77). In further studies they also showed that the F353F allele was more common in preterm infants with BPD than controls (OR 3.6, 95% CI 1.5–8.8,  $p=0.002$ ).

#### 41.3.4 Vascular Genes and BPD

Angiotensin converting enzyme (ACE), located in pulmonary endothelial cells, converts physiologic inactive angiotensin I to active angiotensin II (AGII). AGII functions as a direct vasoconstrictor as well as a stimulator of aldosterone production, which promotes extracellular fluid retention. In addition, recent studies suggest a role for AGII in the inflammatory cascade (91). Increased activity of ACE has been hypothesized to increase the risk of BPD. Yanamandra et al. (17) investigated whether a specific insertion/deletion polymorphism in intron 16 of *ACE*, previously associated with increased enzyme activity, contributed to the risk for BPD. They studied 245 mechanically ventilated infants weighing less than 1250 g at birth, and found no association between the *ACE* insertion/deletion polymorphism on mortality or development of BPD. In a similar, but smaller, study of 51 VLBW (BW less than 1000 g and GA equal to 28 weeks) infants with BPD compared with 60 controls, Kazzi and Quasney (18) found that homozygotes and heterozygotes for the high activity deletion polymorphism were more likely to have BPD than the group without the deletion (47% versus 22%,  $p=0.025$ ). The authors also suggested that the number of activity alleles correlated with severity, but only mild and moderate BPD was analyzed. In contrast, Bodoki et al. found no effect from the DD genotype on BPD in a study of 114 infants of greater GA (30 weeks) (19), perhaps highlighting the effect of GA on the impact of deleterious genetic factors on diseases of prematurity.

Several studies have demonstrated a role for vascular endothelial growth factor (VEGF) in lung angiogenesis and the protection of alveolar damage from hyperoxia, suggesting important roles in the pathogenesis of BPD (92). The *VEGF* 460C allele was associated with a dose-dependent reduction (OR 0.147, 95% CI 0.03–0.86,

$p=0.048$ ) in BPD risk in a cohort of 181 preterm infants, while the T allele had an increased risk of 9% (95% CI 2–14%) above baseline risk, after accounting for sex, GA, and length of supplemental oxygen therapy (32).

Hartel et al. (22) studied several coagulation factors, including factor V Leiden, prothrombin G20210A, factor VII-323 del/ins polymorphism, and factor XIII Val-34Leu polymorphisms. They found that among 1008 preterm infants, BPD was less prevalent in carriers than noncarriers (8.3% versus 14.6%,  $p=0.011$ ) of the factor XIII Val34Leu polymorphism. This polymorphism has been shown to be associated with alterations in the fibrin clot that protects against infarction and thrombus propagation. The authors suggested that the allele may be protective against BPD.

#### 41.3.5 Genes Related to Inflammation and BPD

Interferon gamma (IFN- $\gamma$ ) is a cytokine critical to both innate and adaptive immunity, and functions as the primary activator of macrophages, in addition to stimulating natural killer cells and neutrophils. Bokodi et al. hypothesized that functional variants of IFN- $\gamma$  influenced the risk for various perinatal complications involving immature immune responses (73). The authors found that carriers of the IFN- $\gamma$  T(+874)A allele required less oxygen and ventilatory support than those infants that did not, and that the allele protected against the development of BPD (OR 0.35, 95% CI 0.12–0.99,  $p=0.049$ ).

Bronchoalveolar lavage (BAL) samples from infants with BPD contain many inflammatory mediators (82). Interleukin 4 (IL-4) is a potent anti-inflammatory cytokine that inhibits the production of pro-inflammatory cytokines and chemokines by monocytes and macrophages that are found in BAL samples, suggesting that IL-4 may have a protective effect on the pathogenesis and progression of BPD. Lin et al. (93) investigated activity-altering IL-4 polymorphisms among 224 infants with RDS, but did not find any significant difference between those who developed BPD and those that did not. Interleukin 10 (IL-10) is another inhibitor of pro-inflammatory cytokines that plays a role in the inflammation and apoptosis associated with BPD. Yanamandra et al. (44) could not find any association with the presence of a low-production-related *IL-10* SNP in 294 VLBW infants and the later development of BPD. In addition, Bokodi et al. were unable to correlate any polymorphisms of multiple inflammatory cytokines including IL-1 $\beta$ , IL-6, IL-10, and IL-12, all known to be associated with lung pathology, or BPD or duration of ventilation (36).

Monocyte chemoattractant protein-1 (MCP-1) has been shown to be elevated in the BAL fluid of infants who developed BPD (94), but polymorphisms in the gene investigated by both Adcock et al. and Bokodi et al. (36,45) were associated with neither MCP-1 concentrations nor BPD. Within the innate immune system,

mannose-binding lectin (MBL2) facilitates the activation of the complement system. As infection is a risk factor for the development of BPD, variants of *MLB2* that decrease protein serum levels and function have been shown in two independent studies to influence the risk of BPD (95,96). Macrophage migration inhibitory factor (MIF) is a cytokine that has been shown to promote murine fetal lung development. Prencipe et al. (97) evaluated the *MIF* promoter polymorphism G(-173)C in 103 preterm infants for association with the risk of BPD. This polymorphism, which leads to increased MIF production, was associated with a lower incidence of BPD (OR 0.2, 95% CI 0.04–0.93,  $p=0.03$ ).

Transforming growth factor beta (TGF- $\beta$ ) is an anti-inflammatory molecule that stimulates the proliferation of fibroblasts and smooth muscle cells. While increased expression of TGF- $\beta$ 1 can lead to pathophysiology that mimics BPD in a neonatal mouse model (98), a noncoding polymorphism associated with decreased in vitro production was found to have no effect on the development of BPD in a study of 178 VLBW infants (45). Additionally, Atac et al. (46) prospectively studied the prevalence of the G(915)T variation, known to be associated with decreased TGF- $\beta$  protein levels, in a group of 192 preterm infants, 98 of whom developed BPD. The variation was found to be in Hardy–Weinberg equilibrium in both subjects who developed BPD and those who did not.

Tumor necrosis factor (TNF) plays a principle role in the inflammatory cascade and has been found to be elevated in the BAL fluid of infants who subsequently develop BPD (99). However, when Adcock et al. (45) investigated an SNP related to increased in vivo levels of TNF- $\alpha$  in 178 VLBW infants, they found no difference in the allele frequencies among those infants who developed BPD and those who did not. Likewise, a study by Kazzi et al. (47) showed similar allelic frequencies of TNF- $\alpha$  and TNF- $\beta$  SNPs among infants with and without BPD. The study also suggested that the number of hypofunctional adenine alleles in the TNF $\alpha$ -238 position was inversely correlated with the severity of BPD ( $r=-0.341$ ,  $p=0.003$ ). However, further studies of independent cohorts did not replicate these findings (36,48). Ultimately, a meta-analysis of 804 preterm infants by Chauhan et al. (100) showed that the hypofunctional 308A SNP of TNF- $\alpha$  was not a significant susceptibility factor for BPD (OR 1.04; 95% CI 0.85–1.25).

### 41.3.6 Antioxidant Genes and BPD

Dystroglycan is an extracellular matrix receptor involved in adhesion. This protein plays an important role in wound repair of epithelium, and thus may play a role in the progressive impairment of wound repair capacity that occurs in BPD. Concolino et al. (101) investigated the genotypes of 33 preterm infants and showed that the N494H homozygous genotype was associated with BPD ( $p=0.033$ ).

Glutathione S transferase (GST) is an important enzyme for cellular defense against ROS. SNPs in GST genes have been shown to alter the efficiency of reducing oxidative toxins. A pilot study of 35 BPD cases with 98 controls by Manar et al. (102) showed that BPD patients were less likely to have the more efficient valine/valine isoform and more likely to have the less efficient isoleucine isoform (OR 4.5, 95% CI 1.0–20.7,  $p=0.05$ ). The study was limited in size, resulting in marginal  $p$  values and wide confidence intervals.

### 41.3.7 Growth Factors and BPD

Insulin-like growth factor-I (IGF-I) and its receptor (IGF-IR) mediate both prenatal and postnatal lung growth. Hellstrom et al. (103) reported that low serum IGF-I was associated with BPD in 22 VLBW subjects. Chetty et al. (104) showed that while IGF-I and IGF-IR levels are low in fetal lung tissue, they are upregulated in RDS and BPD. Balogh et al. (63) found no association between a noncoding SNP in *IGF-1R* and BPD in 132 LBW infants, though the methods relating serum IGF-1 levels to the SNP have been called into question by further studies (5).

### 41.3.8 Miscellaneous Genes and BPD

Exposure to hyperoxia has been found to increase the levels of alternatively spliced isoforms of matrix metalloproteinase 16 (MMP16), a protein that plays a role in both lung embryogenesis and repair. After adjusting for BW and ethnic origin, the TT genotype MMP16 C/T (rs2664352) and the GG genotype of MMP16 A/6 (rs2664349) were protective for BPD and associated with decreased levels of the protein in tracheal aspirates of 284 infants born less than 28 weeks GA (105). Urokinase is an enzyme that participates in the stimulation of fibrinolysis and degradation of basement membrane glycoproteins. A 3'-UTR polymorphism was not found to be associated with BPD in a study by Lin et al. (106) of 204 ventilated infants born at less than 30 weeks GA.

### 41.3.9 Summary of BPD

Support for the genetic basis of BPD derives from two studies of twin pairs, showing heritability of 53–82%, depending on severity and definition of disease. A total of 25 candidate genes have been studied to date in variable numbers of subjects, but only 3 have been independently validated (*ACE* (17–19), *MBL2* (95,96), and *SP-B* (57,59–61,90)). Given that the ORs reported for any candidate gene was less than 2.0, it is likely that any combination of the known candidates accounts for less than 5% of the total variance. Of the 25 candidate genes, 18 were in the inflammatory cascade (mostly interleukins or interleukin modulators), and 7 were related to apoptosis. The choice of these genes was guided by what has been observed and described in pathologic specimens.

More expansive genome-wide studies beyond inflammation and apoptosis will likely identify key genetic factors not currently appreciated by conventional candidate approaches.

## 41.4 PATENT DUCTUS ARTERIOSUS

In fetal life, the ductus arteriosus is a patent vessel that diverts blood from the pulmonary artery to the aorta to reduce pulmonary blood flow. Failure to promptly close this muscular artery after birth and establish a mature circulatory pattern is termed persistent or PDA. A PDA frequently complicates the course of preterm infants. In preterm newborns, the PDA remains patent due to excess prostaglandin and nitric oxide sensitivity, the response to inflammatory mediators, and relative resistance to local hypoxia-ischemia (107). A review by Bokenkamp et al. (108) details further animal models of PDA that utilize targeted gene deletions to derive deeper insight into the complex physiology of the closing process.

With the increasing rates of preterm delivery, PDA is now the most common form of congenital heart disease in the newborn period (109), accounting for up to 13.7% of all cases of congenital heart disease (110). The persistence of the ductus in preterm infants, while physiologic in the setting of young GA, is not physiologic to the pulmonary-dependent circulation of the delivered neonate, and thus contributes to significant neonatal morbidity and mortality (111,112). The incidence of PDA in infants with a GA of 24, 25, and 26 weeks was 76.9%, 69.5%, and 61.5%, respectively (113). Risk factors for PDA include prematurity and presence of RDS (109).

### 41.4.1 Heritability of PDA

The contribution of genetic factors to the incidence of PDA in premature infants is increasingly being recognized. In a heritability study on premature twins, Bhandari et al. (114) modeled the genetic and non-genetic factors that contributed to the concordance of PDA among 333 DZ twin pairs and 99 MZ twin pairs from two different institutions. They showed that 76.1% of the variance was attributable to familial factors (genetic plus shared environmental components; 95% CI 62.5–89.8%,  $p=0.001$ ) and that heritability was 12.3%, though not statistically significant (95% CI 0–98%,  $p=0.779$ ).

### 41.4.2 Candidate Genes

There are few studies that investigate solely the effect of single-gene polymorphisms on a preterm child's risk of developing PDA. Derzbach et al. (115) studied the risks for various perinatal conditions related to the estrogen receptor- $\alpha$  gene *ESR1* PvuII marker locus, since premature withdrawal of maternal estrogens has been shown to play a role in preterm morbidity. They reported that

in a group of 141 low birth weight (LBW) neonates, male infants with the p-allele were less likely to have PDA (OR 0.24, 95% CI 0.05–0.97,  $p<0.05$ ). There was no effect of the p-allele on female infants. Altered immune regulation of both the adaptive and innate systems has also been implicated in a host of perinatal morbidities. Bokodi et al. (73) investigated the role of IFN- $\gamma$  and IL-12, which are regulators of macrophages and natural killer cells. In a study of 153 LBW newborns, they showed that the INF- $\gamma$  T(+847)A allele had a protective effect on the development of PDA (OR 0.43, 95% CI 0.19–0.97,  $p=0.043$ ).

In a study more tailored to the specific processes that contribute to PDA, Dagle et al. (116) studied 130 genes linked to the regulation of smooth muscle contraction, xenobiotic detoxification, and inflammation. They tested 377 SNPs in a cohort of 240 premature infants less than 32 weeks GA, and initially identified seven SNPs significantly associated with PDA. The seven SNPs were then tested in an additional 162 subjects, along with the angiotensin II type I receptor variant previously studied by Treszl et al. (117) in relation to indomethacin treatment of full-term infants with PDA. In the second analysis, only two genes remained significantly associated with PDA: the neural crest gene responsible for Char syndrome, called transcription factor AP-2 $\beta$  ( $p=0.003$ ), and a gene that controls NF- $\kappa$ B-mediated inflammation and apoptosis called *TNF-receptor-associated factor 1* ( $p=0.005$ ). Haplotype analysis showed that genetic variations in prostacyclin synthase, which produces the potent vasodilator prostaglandin I<sub>2</sub>, were also associated with PDA ( $p=0.01$ ). Notably in the second analysis, the angiotensin II type I receptor variant was not found to be significantly associated with PDA.

### 41.4.3 Meta-analysis

Treszl et al. (75) used a random forest technique to reanalyze previously published data on 24 SNPs studied in 135 preterm infants. Using relative importance scores, they showed that when including SNP information for *VEGF*(+405)G, *ACE* D, *Ang*(-35)C, and IL-12 p40 GC (all  $IS>1.5$ ,  $p>0.06$ ), the accuracy of predicting the occurrence of PDA improved when compared with a baseline prediction utilizing only GA and BW (0.57–0.64).

### 41.4.4 Genes and Response to Intervention for PDA

Further investigations into the pathogenesis and morbidity of preterm PDA have focused on the effects of single-gene variations on the efficacy of medical management. Treszl et al. (117) studied response to medical management with prophylactic indomethacin—a nonselective cyclooxygenase (COX) inhibitor commonly used to treat persistent PDA in preterm neonates—in

159 preterm infants with PDA. They showed that the CC(1166) genotype of the angiotensin II type I receptor gene (rs5186) conferred a lower risk of PDA than the AA or CA genotypes after early indomethacin administration (OR 0.067, 95% CI 0.005–0.821,  $p=0.035$ ). Durmeyer et al. (118) also used genotype to assess response to medical treatment. They studied whether variants of cytochrome P450 (CYP), known to influence the metabolism of the COX inhibitor ibuprofen, influenced how preterm infants responded to ibuprofen therapy. In their cohort of 111 preterm neonates less than 28 weeks GA with hemodynamically significant PDA, neonates with wild-type CYP2C8 or 2C9 alleles were more likely to respond to ibuprofen therapy compared with neonates with variant CYP2C8 and/or 2C9 (73% versus 52%,  $p=0.04$ ). However, when they compared responders (ductus closure;  $n=75$ ) to non-responders (surgical ligation;  $n=36$ ), the only two factors significantly associated with response to ibuprofen using multivariate analysis were greater GA and non-white race; CYP2C variants were not associated with PDA response to ibuprofen.

#### 41.4.5 Summary of PDA

The influence of genetic factors on the risk for PDA has not yet been definitively shown. A heritability study of 432 twin pairs showed that familial factors, which include both environmental and genetic factors, account for up to 76% of the variance in liability for PDA, while a sub-analysis of heritability was not significant likely due to lack of power. Variations of metabolic genes have been studied for their role in determining efficacy of medical management, though these SNPs were not uniformly shown to significantly affect the outcome of intervention. Studies of genes related to estrogen signaling and immune regulation identified variations that effect the risk for PDA, while a directed query of 377 polymorphisms uniquely selected for their possible role in the pathogenesis identified only three variations (AP-2 $\beta$ , TNF-receptor-associated factor 1, and prostacyclin synthase) that were significantly associated with the presence of PDA. Finally, random forest analysis suggested that, at the very least, certain polymorphisms may be useful in predicting the occurrence of PDA.

### 41.5 INTRAVENTRICULAR HEMORRHAGE

IVH is a major cause of acute brain injury in preterm infants, and can contribute to significant developmental disability and adverse outcomes. The subependymal germinal matrix is a temporary structure, yet critical to the production and maturation of nerve cells in the developing brain. The vasculature that supplies these tissues lacks the mature structure and stability of more permanent vessels, and thus is prone to rupture. IVH occurs during the first 1–3 days after birth, when these vessels

are most delicate (119). The severity of IVH is graded from I to IV, depending on characteristics such as acute distension of the cerebral ventricular system with blood and parenchymal venous infarction. The inflammation, blood pressure instability, and hypoxia associated with preterm birth are factors that are believed to be contributing factors (120).

IVH occurs almost exclusively in infants less than 32 weeks GA or below 1500 g, and is inversely associated with GA. Approximately 25% of infants born below 1500 g develop some form of IVH (120), though as the severity of prematurity increases, the proportion of higher grades of IVH increases (121). A recent large survey of preterm infants demonstrated that overall incidence of IVH was 11, 4, 7, and 5% for grades I, II, III, and IV, successively (83). Risk factors for IVH include young GA, male sex, unstable blood pressure with reperfusion injury, NEC, maternal chorioamnionitis, as well as respiratory complications such as RDS, hypercapnia, and pneumothorax. Antenatal steroids have been shown to decrease the risk (120). The long-term effects of IVH are related to the severity of the hemorrhage; up to three-quarters of children with a history of grade III or IV IVH develop cerebral palsy and/or major intellectual disabilities (120).

#### 41.5.1 Heritability of IVH

In addition to the strong association of GA and environmental factors with the development of IVH, studies of twins have quantified the familial (genetic plus shared environmental) components. An early study of 70 preterm twins by Viscardi et al. (122) showed significant effects of twinship and birth order on the development of IVH. A larger study by Bhandari et al. (86) of 450 preterm twin pairs showed that shared environmental and genetic factors accounted for 41.3% (95% CI 7.0–75.6%,  $p=0.02$ ) of the variance after adjusting for confounders. However, subset analysis of 252 twin pairs for which zygosity data was known did not show significantly different rates of concordance between MZ and DZ pairs, likely due to lack of power. The Bhandari study also confirmed that RDS (OR 3.59, 95% CI 1.85–6.97,  $p=0.001$ ) and GA (OR 0.85, 95% CI 0.73–0.98,  $p=0.02$ ) were significant independent variables for IVH (86). In a small study of 41 twin pairs, Perlman et al. (123) also did not find a difference in concordance for IVH between MZ and DZ twins.

#### 41.5.2 Candidate Genes

There are multiple overlapping factors and genetic pathways that likely contribute to the pathogenesis of IVH. These include angiogenesis and vascular pathology, neonatal cerebral blood flow, inflammation/infection, defense from reactive oxide species, and coagulation/thrombophilia mutations (120). Several studies have looked into genetic variations in these pathways that could predispose a preterm infant to IVH.

### 41.5.3 Hemostasis Genes and IVH

Consensus has not yet been reached on whether hemostasis gene mutations predispose preterm infants to IVH. Hartel et al. (22) investigated factor V Leiden, prothrombin G20210A, factor VII 323 del/ins polymorphism, and factor XIII Val34Leu polymorphisms among 1008 preterm infants, and found that, contrary to other reports, the frequencies of these polymorphisms were not higher in IVH compared to preterm controls. Another large study of 305 preterm neonates by Göpel et al. (23) found that the overall incidence of IVH was equivalent between those infants with factor V Leiden or the prothrombin G20210A mutation compared with controls (18.6% versus 16.4%). However, two factor V Leiden case-control studies have demonstrated increased risk of IVH. The first study by Petäjä et al. (24) of 51 preterm infants found that newborns with IVH were more likely to be carriers of the factor V Leiden Gln506-FV polymorphism than the general population, with an OR of 5.9 for being a carrier (95% CI 1.7–20.3,  $p=0.013$ ). They estimated that the absolute risk of IVH in an infant with factor V Leiden and less than 30 weeks GA was 80%, versus 14% among all infants born before 30 weeks GA. In the second case-control study, Komlosi et al. (25) found that within their group of 130 preterm infants, 10% of infants with grade I IVH had factor V Leiden (G1691A) mutation, versus 4.8% of controls. A separate case report by Ramenghi et al. (124) linked thrombophilic mutations such as in factor V Leiden with germinal matrix IVH (grade I). This report described a 24-week fetus with both factor V Leiden and methylenetetrahydrofolate reductase mutations, with severe ventriculomegaly, and IVH detected via intrauterine magnetic resonance imaging. This rare finding of prenatal IVH suggested a possible role of these mutations in the pathogenesis of preterm IVH.

Aronis et al. (28) studied the prothrombin G20210A mutation individually, and determined that it was more prevalent in a cohort of 17 newborns with IVH than in 38 similarly aged infants without IVH (12% versus 2%), though the difference was not statistically significant.

Göpel et al. (27) studied the factor XIII Val34Leu polymorphism in 531 preterm infants and full-term controls. They found that this polymorphism, known to be associated with decreased risk of adult brain infarct and increased risk of adult intracerebral hemorrhage, was associated with an increased rate of IVH (14.3% in carriers versus 10.1% in infants without the mutation,  $p=0.17$ ) but a decreased risk for isolated IVH and white matter disease in neonates (OR 0.3, 95% CI 0.1–0.7,  $p=0.005$ ). This study suggested that while a weaker clot can increase the rate of IVH (not statistically significant), the pathogenesis of white matter disease subsequent to IVH may rely, at least partially, on the post-hemorrhagic ischemia caused by the clots.

Collagen IV A1 (*COL4A1*) contributes one of the six alpha chains that together form collagen IV, a

critical component of basement membranes. Mutations in *COL4A1* have been shown to result in vascular damage and IVH in neonatal mice and porencephaly (a sequela of white matter damage in grade IV IVH) in human infants (125). Bilguvar et al. described a heterozygous *COL4A1* insertion mutation in 24-week DZ twins who developed grade III and grade IV IVH by day 2 of life (126). In addition, de Vries et al. (127) described a pair of siblings born at 33 and 31 weeks GA, both with antenatal IVH and the same deleterious *COL4A1* mutation inherited from their asymptomatic mother.

### 41.5.4 Genes Related to Inflammation and IVH

The preterm neonate is exposed to environmental insults that stimulate inflammatory factors that may increase the risk of neuronal damage. Variations known to enhance the inflammatory response have been associated with increased risk for developing IVH. A previously discussed study by Adcock et al. (45) investigated the role of variations in inflammatory cytokines in the development of BPD in a group of 178 ventilated preterm infants. While they did not find any significant associations with BPD, they showed that infants with the TNF- $\alpha$  promoter-308A allele (known to increase TNF- $\alpha$  production) had increased risk of IVH (relative risk (RR) 2.07, 95% CI 1.02–4.18,  $p=0.041$ ). Heep et al. (49) studied variations of TNF- $\alpha$  and TNF- $\beta$  in 27 preterm infants less than 32 weeks GA with severe IVH, compared to 102 healthy newborns greater than 32 weeks GA. They found that the male subjects had a significantly higher prevalence of the homozygous genotype (2/2) for the NcoI TNF- $\beta$ 2 allele ( $p<0.001$ ), which has been shown to be a marker for increased TNF- $\alpha$  expression. Notably, there were no significant findings to associate the TNF- $\alpha$  promoter-308 polymorphism with IVH. Another study of the inflammatory cytokine IL-1 $\beta$  by Baier et al. (37) in 215 ventilated preterm infants, found that the *IL-1 $\beta$* -511 T allele (known to increase IL-1 $\beta$  production) was associated with an increased risk for IVH (OR 3.0, 95% CI 1.4–6.4,  $p=0.003$ ).

Further investigations into the role of variations of the pro-inflammatory, neurocytopathogenic cytokine IL-6 have produced contradictory reports. Increased IL-6 production has been associated in neonates with the genotype *IL-6*-174CC. In a study of 148 preterm white infants from Britain, Harding et al. (40) showed that the CC genotype was associated with increased odds of IVH (OR 3.5, 95% CI 1.0–12.2,  $p=0.038$ ), as well as white matter disease and disability. Göpel et al. (41) refute prior studies on the connection between IL-6 variants and risk for IVH. They found that among a larger sample size of 1206 preterm white infants from Germany, the frequency of IVH was statistically equivalent between the three major genotypes at the 174 position. Harding et al. investigated the role of variants at the 572 position of the

IL-6 gene (42) as well. As with position 174, the C allele was associated with higher levels of IL-6. In this study of 113 preterm neonates, they found that although there was decreased long-term cognitive ability in children with the rare *IL-6-572C* allele, there was no increased rate of IVH or white matter disease.

IL-4 has been shown to modulate cytokine production in astrocytes, and increased concentrations can be seen in adult cerebral infarctions. The *IL-4 C(-590)T* variant is associated with increased IL-4 production. Yanamandra et al. (128) showed that the -590 T allele was associated with an increase in severe IVH in 235 preterm black infants from the USA.

Nitric oxide, a product of the endothelial NO synthase (*eNOS*) gene associated with anti-inflammatory and vasodilatory effects, has been found in decreased levels among infants with respiratory conditions and IVH. In a study of 124 preterm black infants from the USA, Vannemreddy et al. (129) showed that infants with IVH and either BPD or RDS had a twofold increase in the -786C mutation (OR 2.3,  $p=0.04$ ), though they did not present a subgroup analysis.

Derzbach et al. (115) tested a polymorphism of the estrogen receptor- $\alpha$  gene *ESR1* PvuII marker locus, due to the connection between premature withdrawal of maternal estrogens and preterm morbidity. In a study of 141 preterm neonates, male infants with the pp genotype had greater risk for IVH (OR 4.39, 95% CI 1.15–16.82,  $p<0.05$ ). There was no effect of the pp genotype on female infants.

### 41.5.5 Summary of IVH

The pathogenesis of IVH has both environmental and genetic elements. Twin studies have generally supported the familial role in determining the risk for IVH, although zygoty data has not yet shown a significant difference in concordance between MZ and DZ pairs, likely due to low power. At least 12 candidate genes have been proposed to play a role in IVH risk. Variants associated with altered coagulation states have been studied with variable results, perhaps reinforcing the nuanced view of IVH as a balance of both infarction and hemorrhage. Studies of inflammatory pathway variants showed contradictory results, but likely play a role. Studies of larger numbers of subjects with sufficient power to stratify for sex, demographics, and GA, will help to delineate the heritability of IVH and identify associated alleles.

## 41.6 RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP), a complication of preterm birth, is a leading cause of impaired vision and blindness in children. Retinal development depends on physiologic hypoxia to stimulate the production of angiogenic factors, such as VEGF and IGF-1, that promote maturation of the retinal vessels. After preterm birth, the hyperoxic environment halts angiogenesis so

that portions of the retina remain relatively avascular. A sharply demarcated boundary between the vascular and avascular retina is the definition of stage 1 ROP, and this becomes an elevated ridge in stage 2. However, as the preterm infant matures, IGF-1 levels rise and permit VEGF to stimulate a new wave of rapid and excessive angiogenesis. This neovascularization creates extra-retinal vessels, which can invade the vitreous (stage 3) or become dilated and tortuous (plus disease). Untreated, the condition can progress to partial (stage 4) or total (stage 5) retinal detachment and severe visual impairment (130).

In the last two decades, many centers have reported a decline in the incidence of ROP, despite an increase in the total numbers of surviving preterm infants. However, ROP has become an epidemic in some countries that provide quality care to preterm infants but lack sophisticated ophthalmologic resources (130). The risk for developing ROP is closely associated with BW and GA. Most infants born prior to 28 weeks GA develop some form of ROP, which can be seen on ophthalmologic examination by 34 weeks GA. Infants born greater than 32 weeks GA are not generally at risk for ROP, while infants born greater than 28 weeks GA will generally develop ROP but not require treatment (131). A recent population-based cohort study showed that the incidence of severe ROP was 10% in preterm infants with less than 32 weeks GA, though only 36% of cases were stage 3 or greater (132). Another multicenter study estimated the incidence of ROP at 68% in infants born less than 1251 g, and 93% in infants born less than 750 g (133). As GA decreases, the incidence and severity of ROP increases. Postnatal risk factors for ROP include IGF-1 levels, postnatal weight gain, sepsis, bradycardia, RDS, BPD, anemia, and IVH (131), but these measures of a “sick baby” apply most significantly to larger infants with older GA (134). Increased arterial oxygen tension also contributes to the development of ROP, due to the adverse effects of relative hyperoxia on the stimulation of normal retinal vessel development (131).

### 41.6.1 Twin Studies

While ROP is a multifactorial disease, there have been several studies suggesting that the risk for ROP is based in part on genetic factors. Variability in the incidence of ROP among different races, sex, and countries is well described and summarized in a review by Holmstrom (135). In addition, genetically modified animal models of ROP (135) emphasize the role of single-gene malfunctions in the pathogenesis. Twin studies of ROP have suggested a strong genetic component to the disease. In 56 twin pairs, Azad et al. (136) showed that 80% of the twin pairs had identical severity in the most severely affected retina, though these findings in twins did not delineate shared environment factors or shared alleles.

### 41.6.2 Heritability of ROP

Bizzarro et al. (137) compared concordance for ROP in 63 MZ and 137 DZ twin pairs in a multicenter study. They showed that GA (OR 0.65, 95% CI 0.45–0.94,  $p=0.024$ ) and duration of oxygen use (OR 1.03, 95% CI 1.01–1.05,  $p=0.003$ ) were significant risk factors for ROP, independent of BPD status. After controlling for both GA and environmental factors, they showed that the heritability was 70.1% (95% CI 9–100%,  $p=0.026$ ).

### 41.6.3 Candidate Genes

Candidate gene studies have focused on known mediators in the pathophysiology, particularly those involving angiogenesis in the developing retina and those linked to genetic syndromes with altered retinal vascularization.

### 41.6.4 Genetic Heterogeneity

Norrie disease is a rare X-linked disorder, due to a deficiency in the Norrie protein, that causes retarded retinal vascularization and a blinding retinopathy (135). There are conflicting results regarding the association of the Norrie disease gene and ROP, possibly due to ethnic differences between study populations. Small studies have identified Norrie mutations in 3–25% of preterm infants with ROP (138–140), although the largest study of 143 subjects by Hutcheson et al. reported that the prevalence of Norrie polymorphisms in infants with severe ROP was not significantly higher than the general population (141), concluding that the polymorphisms did not appear to be a major causative factor in the pathogenesis. Kim et al. (142) did not identify a single Norrie polymorphism among 18 Korean preterm infants with ROP. Additionally, Haider et al. (143,144) found no association between Norrie mutations and ROP in groups of 102 and 210 premature Kuwaiti infants, though a later study (145) of the same cohort of 210 infants showed a 5'-UTR polymorphism in the Norrie gene (C(597)A) that was associated with severe ROP. The AA genotype was found in 83.3% of severe ROP cases, 0% of spontaneously regressing ROP, and 10.4% of control cases ( $p<0.0001$ ). Dickinson et al. (146) identified deletions within the CT repeat region of the Norrie gene in three subjects with regressed ROP in a cohort of 31 Australian preterm infants with ROP and 91 preterm controls. The authors concluded, however, that these deletions did not contribute to severe ROP in their cohort.

Familial exudative vitreoretinopathy (FEVR) is another disorder with a pathogenesis similar to ROP. FEVR is a genetically heterogeneous bilateral eye disease that arises from deficient retinal vascularization in full-term infants. Mutations in the Norrie disease genes cause an X-linked form of FEVR. Four genes along the beta-catenin-mediated Wnt signaling pathway (*NDP*, *FZD4*, *LRP5*, and *TSPAN12*) have been implicated in retinal

vasculogenesis and in the pathogenesis of non-X-linked FEVR. Several studies of preterm infants have shown that a small percentage with severe ROP (3–11%) have variants in the same genes that can lead to FEVR, suggesting that alterations in the Wnt pathway may play a role in the abnormal retinal angiogenesis observed in both conditions (147).

### 41.6.5 Vascular Genes and ROP

Variations of the *VEGF* gene that affect protein production have been described in ROP. Cooke et al. (35) studied *VEGF* variants in 91 preterm infants with treatment-threshold ROP, and found that a significant number of ROP infants had the *VEGF* G(-634)C polymorphism (position also referred to as +405) compared with 97 controls without disease ( $p=0.03$ ). In addition, they noted that the G allele was a significant independent predictor of progression to threshold ROP ( $p=0.008$ ) and that infants with the GG genotype, associated with increased *VEGF* expression, were twice as likely to have threshold ROP (OR 2.0, 95% CI 1.11–3.69). Vannay et al. (29) studied 86 preterm infants that had been treated for ROP, and compared them with 115 preterm infants with ROP that did not require therapy. They found that the -634 C allele was significantly more common among infants with severe treatment-threshold ROP, doubling the risk for heterozygotes (-634 C OR 2.00, 95% CI 1.02–3.92,  $p=0.04$ ) and tripling the risk for homozygotes respectively (-634 C/C OR 3.37, 95% CI 1.17–9.65,  $p=0.007$ ). In addition, the 460TT/634CC haplotype was more prevalent in the treated patients (15% versus 1%,  $p<0.001$ ), and the association remained significant when risk factors such as GA, supplemental oxygen use, and sex were incorporated into the model. Kwinta et al. (33) also studied *VEGF* genotypes in 161 preterm infants, divided into three groups based on ROP severity: none, mild without treatment, and severe requiring treatment. The -460 T allele was overrepresented in the ROP treatment group compared to the group without ROP (54.2% versus 42.6%, OR 1.63, 95% CI 1.03–2.55).

However, these *VEGF*-ROP associations were not replicated in other studies. Shastry et al. (34) found no significant difference in the frequencies of *VEGF* G(-634) C and C(-460)T alleles in 61 preterm infants with advanced ROP compared to 61 full-term adult controls. The Kwinta study (33), discussed above, showed no association between the *VEGF* G(-634)C allele and ROP. In a study of 200 preterm infants, Banyasz et al. (30) did not find an association between the *VEGF*-2578 A allele and ROP, but their data suggested that -2578 A allele may affect severity in preterm males ( $p=0.044$ ) (30).

In another example of conflicting results, an *ACE* gene insertion/deletion (I/D) polymorphism was shown to play a role in ROP in a study of 181 preterm Kuwaiti infants by Haider et al. (20). They found that the I/I

genotype was more prevalent in ROP cases compared to non-ROP controls (24% versus 7%,  $p < 0.001$ ). However, the prevalence of the D/D genotype, associated with higher serum ACE concentration, was higher in ROP cases needing therapy (63%) compared with ROP cases that spontaneously regressed (63% versus 36%,  $p < 0.04$ ). The investigators postulated that the I allele increased risk for ROP, while the D allele and the higher levels of ACE increased risk for retina damage and neovascularization. In contrast, Spiegler et al. (21) studied the ACE I/D variant as well as the AGTR1 1166 A/C polymorphism in a cohort of 1100 preterm infants and found no significant associations with ROP.

In a study of 455 SNPs from 153 genes in 347 infants less than 32 weeks GA, Mohamed et al. (148) identified five genes associated with ROP with  $p$ -values less than 0.01, including the T(+867)G (rs427832) allele of AGTR1 ( $p = 0.005$ ), in support of Haider et al. The other four genes were: Indian hedgehog (IHH), related to vasculogenesis ( $p = 0.003$ ); T-box transcription factor of mesoderm (TBX5;  $p = 0.003$ ); cholesterol ester transfer protein (CETP;  $p = 0.004$ ); and glycoprotein 1b alpha polypeptide (GP1BA), a platelet surface protein ( $p = 0.005$ ). None of these five associations, however, withstood correction for multiple testing. In a multiple logistic regression analysis controlled for significant clinical risk factors, the Mohamed (148) study also showed that two variants of complement factor H (CFH) conferred protection against ROP (T allele for both variants,  $p = 0.01$ ). Both CFH variants were previously associated with neovascularization in macular degeneration. In addition, a polymorphism of the EPAS1 gene, a vascular endothelial cell transcription factor that activates VEGF function in response to hypoxia, was associated with ROP in the logistic regression analysis ( $p = 0.001$ ), while another EPAS1 polymorphism was identified through a family-based analysis strategy ( $p = 0.007$ ).

eNOS plays a central role in retinal angiogenesis and vasculogenesis. Rusai et al. (149) investigated the role of known functional polymorphisms of eNOS in the pathogenesis of ROP. In a study of 105 premature infants with treated ROP and 127 preterm infants with stage I/II ROP, they found that the genotype distribution of the eNOS 27-bp repeat polymorphism (b/a) was significantly different ( $p = 0.015$ ), and a multiple logistic regression analysis showed that male sex ( $p = 0.046$ ) and eNOS aa genotype ( $p = 0.047$  versus ab and  $p = 0.022$  versus bb) were significantly associated with severe ROP. Other studies have not shown any association between ROP and polymorphisms of TNF- $\alpha$ , TGF- $\beta$  (35), IGF-IR (62,150), or ANG2 (30,151).

#### 41.6.6 Meta-analysis

In a study by Dunai et al. (152), random forest analysis was used to evaluate whether previously investigated polymorphisms of genes that are thought to contribute to

the pathogenesis of ROP could be predictive of ROP at birth. A cohort of 103 preterm infants with ROP requiring treatment and 134 preterm controls was genotyped for seven polymorphisms (VEGF T(-460)C, VEGF G(-634)C, IGF-IR G(+3174)A, ANGII G(-35)C, ESR1 PvuII Pp, and eNOS 27-bp b/a). The genomic data was combined with birth data, and the resulting analysis suggested that the most important predictors of ROP were prematurity, LBW, intrauterine growth retardation, and Apgar scores. The polymorphisms were significantly less important than GA, LBW, intrauterine growth retardation, and Apgar scores for predicting the risk of treatment-threshold ROP.

#### 41.6.7 Summary of ROP

The genetic basis of ROP is supported by severity and heritability studies of 250 twin pairs. One study of 63 MZ and 137 DZ twins showed a heritability of 70%. Candidate gene studies have further investigated the role of genetic polymorphisms on the pathogenesis and risk. Genetic disorders with pathology similar to ROP have directed studies that have described associations between Norrie and FEVR mutations with ROP, although these findings were not reproduced in other studies. Similarly, some studies of genes related to vasculogenesis, including VEGF and angiotensin, identified associations with ROP but were not confirmed in other studies. A larger study of 455 SNPs in 153 candidate genes identified five polymorphisms associated with ROP, but they did not withstand correction for multiple testing. A meta-analysis of seven variants from vascular (VEGF, ANGII, eNOS), inflammation (IGF-IR), and estrogen receptor (ESR1) genes showed that polymorphisms of these genes were significantly less important than GA, LBW, intrauterine growth retardation, and Apgar scores for predicting the risk of treatment-threshold ROP.

### 41.7 NECROTIZING ENTEROCOLITIS

NEC is a common complication of prematurity and a cause of significant morbidity and mortality. The gastrointestinal tract of the preterm infant is immature in many ways: intestinal motility and absorption, barrier defenses, immune function, and mesenteric circulatory regulation. While the mechanism remains unknown, it is thought that these factors combine to result in a constellation of symptoms called NEC. Early signs of NEC include abdominal distention, feeding intolerance, and bloody stools, usually within the first 8–10 days of life. Radiographic signs progress from dilated loops of stagnant bowel to pneumatosis intestinalis and portal venous gas. Late-stage disease is characterized by peritonitis, bowel ischemia, and systemic hypotension. There are several unproven hypotheses that seek to explain the pathogenesis, including hypoxia-ischemia, altered microbial colonization, and intestinal immune dysregulation resulting in excessive inflammatory responses to bacteria (153).

Approximately 7% of infants born between 500 and 1500 g develop NEC, based on studies of large, multicenter neonatal network databases (154,155). This incidence is somewhat increased from prior decades, most likely due to advancements in perinatal care that allow for longer survival of very preterm infants. Many studies have attempted to define determinants of NEC risk; the only consistently identified risk factors are BW and GA. Feeding with human milk has been suggested to be protective, with up to a 10-fold reduction in risk (156). Age of onset varies inversely with GA, and the risk remains high in preterm infants until a GA of 35 weeks (157). The rate of death associated with NEC ranges between 20 and 30%, with higher rates found among infants who underwent surgical treatment (158).

### 41.7.1 Heritability of NEC

In a multicenter retrospective study of 450 preterm twin pairs, Bhandari et al. (86) confirmed that GA was a major determinant of NEC risk (OR 0.82, 95% CI 0.68–0.99,  $p=0.03$ ). After controlling for GA, the shared familial (genetic and environmental) contribution to the risk of NEC was 51.9% (95% CI 33.2–70.6%,  $p<0.001$ ), however the study lacked power to determine heritability.

### 41.7.2 Candidate Genes

Associations with candidate genes have been identified for NEC. Derzbach et al. (115) studied the association of the PvuII pP polymorphism of the estrogen receptor- $\alpha$  gene in a cohort of 141 preterm infants and 167 full-term controls. Male infants with the p allele were found to be at lower risk for NEC than males carrying the P allele (OR 0.24, 95% CI 0.07–0.83,  $p<0.05$ ). Bokodi et al. (73) studied a functional polymorphism of IL-12, which is an IFN- $\gamma$ -stimulating cytokine, in 153 premature infants with NEC compared with a control group of 172 healthy full-term infants. They showed that carriers of the IL-12 p40 CTCTAA allele were at increased risk for NEC (OR 2.37, 95% CI 1.01–5.53,  $p=0.046$ ). Heterozygote carriers of the IL-12 CTCTAA/GC polymorphism were also at increased risk (OR 2.91, 95% CI 1.41–6.02,  $p=0.004$ ). Treszl et al. (39) evaluated the frequency of a functional polymorphism of another cytokine, IL-4 receptor  $\alpha$  (IL-4R $\alpha$ ), in 46 preterm infants with NEC. They found that infants with NEC carried the variant less frequently than 90 preterm controls (12.5% versus 22.4%,  $p<0.05$ ), after adjusting for risk factors, and postulated that infants carrying this allele might have a predominance of Th2 cells that may protect against NEC.

Studies have noted decreased levels of L-arginine in children with NEC. Moonen et al. (159) studied the effect of a carbamoyl-phosphate synthetase 1 (*CPS1*) polymorphism that has been associated with low concentrations of L-arginine in neonates. They analyzed

the *CPS1* T(1405)N polymorphism in a cohort of 17 preterm infants with NEC, 34 preterm infants without NEC, and 25 healthy full-term infants. The incidence of NEC was found to correlate with the number of C alleles ( $p=0.037$ ), and the CC genotype was associated with an increased risk (OR 3.43, 95% CI 1.01–11.49,  $p=0.048$ ).

### 41.7.3 Vascular Genes and NEC

Banyasz et al. (31) studied functional polymorphisms of *VEGF*, which is a potent stimulator of vasculogenesis. In their study of 128 premature neonates and 200 healthy full-term infants, the *VEGF*-2578A allele was a risk factor (OR 2.77, 95% CI 1.00–7.65). Thrombosis of large mesenteric vessels is occasionally noted in some surgical cases of NEC. To investigate if pro-thrombotic genetic conditions play a role in the pathogenesis, Göpel et al. (26) sequenced the factor V Leiden mutation in a retrospective case-control study of 39 preterm infants with NEC. While one case of factor V Leiden was found in an infant noted to have thrombus in the mesenteric vein intraoperatively, the control group also had a single case of asymptomatic factor V Leiden, which coincides with the expected mutation frequency of approximately 5% in the general population.

### 41.7.4 Genes Related to Inflammation and NEC

Henderson et al. (38) studied the association of cytokine polymorphisms in the pathogenesis of NEC. In a multicenter case-control study of 100 preterm infants, they genotyped 10 candidate cytokine SNPs previously associated with infectious and inflammatory disease processes (TNF, IL-1 $\beta$ , IL-4R $\alpha$ , IL-6, IL-8, IL-10, IL-18), but found no significant association with NEC.

### 41.7.5 Meta-analysis

Findings from the Henderson study (38) described above were included in a random effects meta-analysis of prior genetic association studies, which increased the precision of the effect size, but did not identify any further associations (38). Treszl et al. (75) used a random forest technique to reanalyze previously published data of 24 SNPs in 135 preterm infants. Using relative importance scores, they showed that when including SNP information for IL-12 p40 GC, *IL-10*(-1082)C, *VEGF*(-460)C, and *ACE* D (all  $IS>1.7$ ,  $p>0.04$ ), the accuracy of predicting the occurrence of NEC increased when compared to a baseline prediction utilizing GA and BW (0.60–0.70).

### 41.7.6 Summary of NEC

While the familial susceptibility to NEC is close to 50%, studies to date have lacked power to determine heritability. However, polymorphisms of estrogen receptors,

interleukins, and metabolic enzymes have been found to be significantly associated with risk in single unreplicated studies. Investigations seeking to link NEC with the processes of vasculogenesis and coagulation through functional polymorphisms have found significant associations as well. An analysis of previously published SNPs associated with prematurity found that four polymorphisms (IL-12 p40 GC, IL-10(-1082)C, VEGF(-460) C, and ACE D) involving inflammation, vasculogenesis, and angiotensin could be used to improve the accuracy of predicting the development of NEC. An alternative meta-analysis found no statistically significant association between NEC and polymorphisms associated with infectious and inflammatory diseases.

### Biographies

**Dr Aaron Prosnitz** graduated Magna Cum Laude with Honors in Biology from Brown University in Providence, RI, and then went on to complete a year of genetics research on autism at Mount Sinai School of Medicine in New York City. Afterward, he underwent medical school education at the University of Pennsylvania School of Medicine in Philadelphia, during which he participated in a NASPGHAN Medical Student Summer Research Fellowship. While finishing his first year of a residency in pediatrics at the Yale–New Haven Children’s Hospital in New Haven, CT, he presented original clinical research on pediatric Crohn disease at the PAS/SPR 2011 meeting. Upon completion of his residency training in 2013, he looks forward to entering fellowship to continue his career in academic medicine and research.

**Jeffrey R Gruen, MD**, is Professor of Pediatrics, Genetics, and Investigative Medicine at the Yale University School of Medicine and the Yale Child Health Research Center. He is a graduate of the Tulane University School of Medicine, and completed residency in pediatrics at Yale–New Haven Hospital. He completed fellowship training in neonatal medicine at Yale Medical School, while undertaking scientific training in molecular genetics. During fellowship, Dr Gruen mapped the short arm of human chromosome 6, including the major histocompatibility complex and hemochromatosis locus on 6p21.3. Later he shifted his mapping studies further up chromosome 6 to the *DYX2* locus for dyslexia, where he identified *DCDC2* as an important gene for dyslexia. Currently, the main focus of his lab is the genetics of language acquisition, reading, and dyslexia. In addition to mentoring graduate students and post-docs in genetics, Dr Gruen continues to attend as a neonatologist in the Newborn Intensive Care Unit of the Children’s Hospital at Yale–New Haven.

**Dr Vineet Bhandari** attended medical school at the Armed Forces Medical College, Pune, India, and then went on to do his pediatric and neonatology training at the Post Graduate Institute of Medical Education and Research, Chandigarh, India. He completed residency in pediatrics and fellowship training in neonatal–perinatal medicine at the University of Connecticut. He is board-certified in both pediatrics and neonatology by the American Board of Pediatrics. He is currently Associate Professor of Pediatrics, Obstetrics, Gynecology, and Reproductive Sciences at the Yale University School of Medicine and Director of the Program in Perinatal Research. He is also an attending neonatologist at the Yale–New Haven Children’s Hospital.

## Disorders of DNA Repair and Metabolism

*Sharon E Plon*

Texas Children's Cancer Center, Texas Children's Hospital; Departments of Pediatrics and Molecular and Human Genetics, Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA

### 42.1 MENDELIAN PATTERN OF INHERITANCE

Somatic cells from patients with DNA repair deficiency syndromes often demonstrate an absence of repair activity and thus these syndromes result from autosomal or X-linked recessive mutations. Typically, individuals who inherit a single heterozygous inactivating mutation in a DNA repair gene are healthy and referred to as carriers. Overall, these autosomal recessive disorders that result in susceptibility to cancer are much rarer than the autosomal dominant cancer susceptibility disorders. Patients carrying founder mutations or families with consanguinity are seen frequently.

For some disorders, there can be multiple mechanisms of inheritance leading to a similar clinical phenotype. For example, disorders of telomere maintenance are often lumped together under the term dyskeratosis congenita, but can result from both recessive (autosomal and X-linked) and dominant mutation mechanisms (1). There is not enough data to know if the dominant disorders are secondary to dosage sensitivity for the heterozygous genes, e.g. *TINF2*, or secondary to a dominant negative impact of the heterozygous mutation. Work reported since approximately 2000 has defined a number of cases where distinct dominant and recessive cancer susceptibility syndromes are associated with mutations in the same gene. In these conditions, heterozygous parents have an adult-onset cancer phenotype with incomplete penetrance, whereas the children who inherit homozygous or compound heterozygous mutations (referred to here as biallelic mutations) have a significant cancer risk in childhood and may demonstrate congenital anomalies, developmental delay, and/or dermatologic features. Thus, there are an increasing number of disorders with a mixed model of inheritance where the cancer-susceptibility phenotype depends on whether the patient carries mutations in one or two alleles of the same DNA repair or metabolism gene.

### 42.2 DISORDERS OF NUCLEOTIDE EXCISION REPAIR: XERODERMA PIGMENTOSUM AND COCKAYNE SYNDROME

Xeroderma pigmentosum (XP) was one of the first genetic disorders to be recognized for its underlying DNA excision repair defect (2). Investigators at the US National Institutes of Health have carried out detailed characterization of the clinical phenotype and molecular abnormalities (3). Most striking are features related to cutaneous sensitivity to ultraviolet (UV) light, including very early onset of telangiectasia and freckling (4). The UV-light-exposed areas of the eye, including the cornea, lids, and conjunctivae, are affected with both corneal clouding and ocular malignancies. The clearest demonstration of the increased mutagenesis by UV light is the over three logs of increased risk of basal and squamous-cell skin carcinomas in sun-exposed areas. The age of onset, beginning in very early childhood, is nearly 40 years earlier than the general population (3). Melanoma skin cancers are also increased (approximately 5% lifetime risk). The specificity for increased cancer risk in sun-exposed areas is highlighted by the relatively modest increase in cancer risk for internal malignancies.

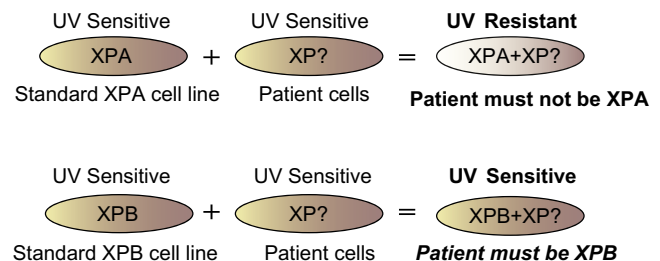

Nucleotide excision repair (NER) is one of the most important mechanisms for correcting the DNA adducts, including thymine dimers, that form after exposure to ultraviolet light (5). Detailed biochemical assays and analysis of XP patients from different complementation groups has allowed discernment of the protein complexes required to complete nucleotide excision repair (Figure 42-1) (6). As is true for a variety of DNA repair disorders, patients who carry mutations in genes that encode proteins that function together as a protein complex often demonstrate a similar clinical phenotype. For a newly diagnosed patient, complementation

**FIGURE 42-1** An outline of the nucleotide excision repair pathway, which includes global genomic repair (1B) and transcription-coupled repair (1A). The damaged base in the DNA is indicated by a green star. In global genomic repair, the damage is recognized by the heterotrimeric complex of XPC, RD23B, and centrin 2, whereas when the damage is in a gene that is being actively transcribed by RNA pol II, the Cockayne syndrome factors ERCC8 and ERCC6 have a crucial role in stalling the transcription process so that repair of the transcribed gene can be initiated. From this point onwards, the repair pathway is common to both mechanisms, and it proceeds by recruiting several other factors, as shown in (2), to effect unwinding, bubble formation of the strand harboring the damage, incision of the strand at discrete points on the 5' and 3' sides, and excision of the fragment containing the damage. The size of the bubble will depend on the nature of damage, which in turn is likely to determine the incision points for the removal of the damaged portion. In step (3), the gap created by the excision of the damaged strand is resynthesized by DNA pol  $\delta/\epsilon$ , with the help of auxiliary factors such as PCNA and RPA-RFC. Finally, DNA ligase I ligates the newly synthesized fragment to the downstream strand to complete the repair process and yield the repaired product (4). DDB1 = xeroderma pigmentosum E; ERCC1 = DNA excision repair protein ERCC-1; ERCC2–5 = excision repair complementing factors (formerly known as XPD/XPB/XPF/XPG); ERCC6/8 = Cockayne syndrome factor B/A; PCNA = proliferating cell nuclear antigen; pol  $\delta/\epsilon$  = polymerase  $\delta/\epsilon$ ; RD23B = RAD23 homolog B (*Saccharomyces cerevisiae*); RFC = replication factor C; RNA pol II = RNA polymerase II; RPA = replication protein A; TFIIH = active transcription complex; XPA = xeroderma pigmentosum A; XPC = xeroderma pigmentosum C. (From Rao, K. S. *Mechanisms of Disease: DNA Repair Defects and Neurological Disease*. Nat. Clin. Pract. Neurol. 2007, 3, 162–172.)

analysis is still used to determine which gene may be defective. Complementation analysis is carried out by fusing fibroblasts from a patient to standardized control cell lines from patients with known defects, and then assaying the fusion cells for restoration of NER (Figure 42-2). Although time-consuming and technically difficult, complementation analysis remains the primary tool used to differentiate the underlying mechanism in many DNA repair disorders because of the ability to test cells from patients for the specific repair defect.

Approximately 20% of XP patients have neurologic problems (3,6). This includes a group of XP patients (often in complementation group A) with neurologic abnormalities described as DeSanctis–Cacchione

**FIGURE 42-2** Complementation assay using UV sensitivity for cells from patients with xeroderma pigmentosum. The patient sample is fused to standard cell lines from each XP subtype. If the fusion cells demonstrate restored UV resistance, then the patient must carry a mutation in another subtype. If fusion cells do not restore UV resistance, then the patient carries mutations in the same subtype. (Modified from Plon, S. E. *Cancer Genetics and Molecular Oncology*. In *Principles of Molecular Medicine*, 2nd ed.; Humana Press, 2006.)

syndrome. In addition to the dermatologic features, patients have early onset progressive neurologic degeneration and immature sexual development. Some complementation group D patients with XP and later onset of neurologic difficulties also manifest brittle hair and ichthyosis, in a condition termed XPD/trichothiodystrophy (TTD). Cockayne syndrome shares some of the UV hypersensitivity of XP, but is also characterized by neurologic deficits, including developmental delay without skin cancer risk. There are at least three complementation groups for Cockayne syndrome. Utilizing knowledge of the specific biochemical defects in cells from patients with either XP or Cockayne syndrome, the genes responsible for this condition (*ERCC2*, 6, and 8) have been cloned (7). In a normal cell, DNA damage in actively transcribed genes is preferentially repaired before DNA from inactive parts of the genome, a process termed transcription-coupled repair (TCR). Cells from Cockayne patients are deficient in TCR, most commonly due to a mutation in the *ERCC2*-encoded DNA helicase, which is also a component of the active transcription complex TFIIH. The neurologic deficits in Cockayne syndrome may be attributed to the high transcriptional load of cells in the nervous system, and thus the central nervous system (CNS) may be more dependent on efficient TCR activity (6); although TCR is deficient the global repair rates are normal in cells from patients with Cockayne syndrome. This may explain the lack of cancer predisposition in this group of patients, which is in stark contrast to the high cancer rates described above for other forms of XP.

Another group of patients classified as XP variant, or XP<sup>v</sup>, demonstrate UV sensitivity but have normal nucleotide excision repair activity when tested in vitro. This disorder is due to mutation of a specialized DNA polymerase,  $\eta$ , belonging to the Y family of DNA polymerases, which function to place two adenine residues opposite a thymine dimer photoproduct, thus restoring the normal base sequence and reducing UV-induced mutagenesis (8).

### 42.3 DISORDERS OF BASE EXCISION REPAIR: *MUTYH* AND COLON CANCER RISK

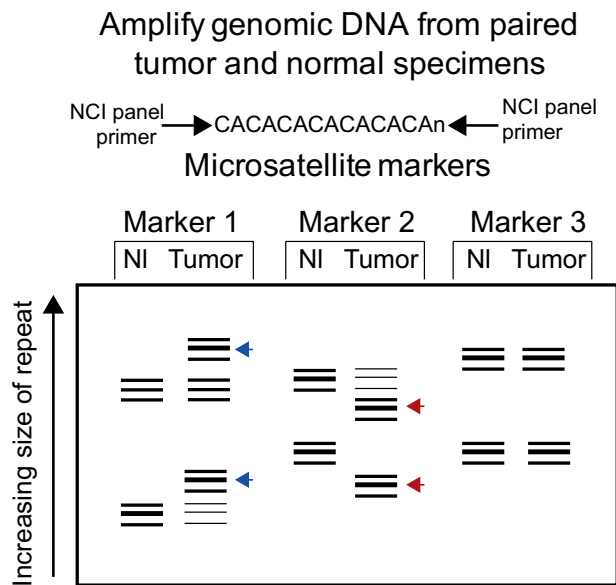

Inheriting mutations in the *MUTYH* base excision repair gene results in a limited range of tissue specificity with regard to cancer risk in the absence of other clinical features. This disorder was discovered through analysis of rare individuals and families in which affected members demonstrate an apparently autosomal recessive form of adenomatous polyposis coli, associated with the development of hundreds of colonic polyps and a high risk of colon cancer (9,10). Elegant work analyzing the tumors from these individuals revealed a somatic mutation pattern consistent with deficiency in base excision

repair, and eventually led to the identification of constitutional biallelic mutations in the *MUTYH* repair gene (also referred to as *MYH*). Specific mutations (Y165C and G382D) in the *MUTYH* gene are quite frequently detected in affected individuals (11). Analysis of cancer rates in individuals who carry one or two copies of these specific *MUTYH* mutations has been performed by a number of investigators. Homozygous or compound heterozygous mutation carriers develop hundreds of adenomatous polyps and have over 100-fold relative risk of colon cancer compared with the general population. Meta-analyses of multiple studies reveal that heterozygous carriers of a single *MUTYH* founder mutation may have at most a small increase in colon cancer rate compared with the general population (relative risk of 1.1–1.4) (12,13). In a population-based study of colon cancer in Canada, Croitoru et al. went further and sequenced the complete *MUTYH* coding region in heterozygous carriers of Y165C or G382D mutations (14). Their analysis yielded an odds ratio (OR) of 1.4 for colon cancer in this smaller group of validated heterozygous Y165C or G382D mutation carriers, but did not reach statistical significance; however, analysis of colon cancers from the heterozygous carriers did reveal somatic inactivation of the wild-type copy of *MUTYH* in 47% of samples tested (14). Thus, *MUTYH*-associated polyposis is an autosomal recessive colon cancer disorder with at most a minor cancer phenotype in heterozygous carriers.

In patients with XP, the predominant sites of cancer are explained by those tissues that are exposed to UV radiation and thus have a higher mutational load. In patients with *MUTYH* deficiency, there is also a very limited tissue spectrum, predominantly of benign and malignant tumors of the colonic epithelia without evidence for a significantly increased risk of other tumor types. This limited spectrum is despite the universal expression of *MUTYH* protein in different tissue types. Possible explanations for this tissue specificity include (1) that exposure of colonic epithelia to mutagens in food may increase the need for efficient base excision repair; or (2) in most tissues, other DNA repair pathways can substitute for *MUTYH*-dependent base excision repair.

### 42.4 DISORDERS OF MISMATCH REPAIR: LYNCH SYNDROME AND TURCOT SYNDROME

Lynch syndrome, with susceptibility to adult-onset cancers, including colorectal, endometrial, and ovarian, results from inheritance of a heterozygous mutation in one of four different mismatch repair genes: *MSH2*, *MLH1*, *MSH6*, and *PMS2* (15). These proteins function in heterodimers to recognize and repair mismatches caused by replication errors. Due to the striking colon cancer phenotype, Lynch syndrome is often referred to as hereditary non-polyposis colon cancer (HNPCC). The lifetime incidence of colon and endometrial cancers is

**FIGURE 42-3** Schematic diagram of a microsatellite instability assay used to evaluate tumor specimens in comparison to normal tissue from patients suspected of having Lynch syndrome or hereditary non-polyposis colon cancer. Microsatellite markers from the National Cancer Institute approved panel are analyzed from paired sets of normal and tumor tissue. Marker 1 and 2 show gain (blue arrowheads) or loss (red arrowheads) of repeat size in the tumor compared with the normal tissue, and are said to demonstrate microsatellite instability.

estimated to be 67–70%, with age of onset beginning in young adulthood and clustering in the 5th to 6th decades. There is also increased relative risk of ovarian, brain, biliary tract, and urinary tract cancers compared with the general population.

HNPCC results from inheriting a single deleterious mutation followed by second somatic inactivating event in the same gene through mutation, loss, or epigenetic silencing. Tumors from patients with HNPCC display an unusual DNA pattern, termed microsatellite instability (MSI) or replication errors positive (RER+), characterized by changes (both increases and decreases) in the length of repetitive sequences spread throughout the genome, due to mismatch repair deficiency in the tumor cell (Figure 42-3) (16). The presence of MSI or expression of mismatch repair (MMR) proteins in the tumor tissue is used to make decisions about germline testing in colon cancer patients. This represents one of the few examples where the molecular diagnostic test relies on a direct assessment of the localized repair deficiency in the tumor environment, as assessed by the number of microsatellite markers in the National Cancer Institute panel that demonstrate instability. Colon cancer incidence in heterozygous carriers of *MSH6* and *PMS2* mutations is lower than in carriers of *MSH2* and *MLH1* mutations (17–20). Thus, *MSH6* protein may play a subtly different biochemical role in mismatch repair than *MLH1* or *MSH2* proteins, as evidenced by the difference in cancer risk and the more frequent instability of mononucleotide repeats compared with dinucleotide repeats in tumors from *MSH6* mutation carriers (18).

The eponym “Turcot syndrome” has been associated with an overlapping set of conditions that presents with colonic polyposis, colon cancer, and brain tumors in childhood, and includes conditions transmitted in both autosomal dominant and recessive forms (21). The autosomal recessive form of Turcot syndrome is also designated “mismatch repair deficiency syndrome” (MMR-D), to clarify its distinct clinical phenotype from the dominant forms of Turcot syndrome (22,23). MMR-D syndrome describes children who inherit homozygous or compound heterozygous mutations in the same MMR genes (*MSH2*, *MLH1*, *MSH6*, and *PMS2*) as those associated with HNPCC. These children have a profound clinical phenotype resulting from mismatch repair deficiency in all cells of the body, including café au lait spots and axillary freckling usually associated with neurofibromatosis type 1 (24).

Tragically, children with MMR deficiency syndrome have a strikingly higher cancer incidence and tissue distribution compared with that of adults with HNPCC. Table 42-2 summarizes the cancer that developed in children documented to inherit two mutations in MMR genes (23). Among this group, the most common cancers were leukemias or lymphomas, brain tumors, and colorectal cancers. Mutations in *MSH2* and *MLH1* resulted in an earlier age of onset and somewhat different pattern of cancers compared with *MSH6* and *PMS2* carriers. All four types of MMR-D are associated with café au lait spots and childhood onset of one or more malignancies (22). Thus, complete deficiency of any one of the MMR proteins in somatic cells has a profound impact on genomic stability and cancer incidence.

The prevalence of childhood leukemias and lymphomas in MMR deficiency syndrome patients clearly demonstrates that the hematopoietic tissues are susceptible to malignant transformation when mismatch repair activity is absent. Mouse models have also demonstrated that *Msh2* homozygous null mice develop lymphomas, but not heterozygous *Msh2* mice (25). Similarly, careful analyses of HNPCC kindreds heterozygous for MMR gene mutations have not revealed an increased risk of hematopoietic cancers during childhood or adulthood (26). The differences in tumor types between individuals who inherit two or one mismatch repair gene mutation may reflect differential rates of second hits in different tumor types. For example, hematopoietic tissues may have a low spontaneous rate of second hits in the general population. Evidence to support this hypothesis that exogenous damage to hematopoietic tissues is needed to inactivate the MMR genes includes the finding that primary leukemias rarely demonstrate MSI, whereas samples from patients with therapy-related secondary leukemias (leukemia that develops after exposure of the patient to chemotherapy treatment for another cancer) demonstrate an MSI-high genotype (27).

The use of microsatellite assays focuses attention on alteration in short repeat sequences due to errors or

**TABLE 42-1 Representative DNA Repair Disorders**

Pathway	Representative Condition	Major Clinical Features	Diagnostic Test(s)
Nucleotide excision repair	Xeroderma pigmentosum	Extreme sunburns, early onset of skin cancers and photo-aging of skin	Sensitivity to UV light in fibroblasts
Base excision repair	MUTYH-associated polyposis	Development of hundreds of adenomatous polyps and early onset colon cancer	Directed mutation analysis of <i>MUTYH</i> sequence
Mismatch repair (See Table 42-2 for description of biallelic form)	Lynch syndrome (hereditary non-polyposis colon cancer)	Increased risk and earlier onset of colon, endometrial, ovarian, and biliary tract cancers	Microsatellite instability in tumor tissue
Double strand break recognition and repair	Ataxia-telangiectasia	Cerebella ataxia, telangiectasia, immunodeficiency, leukemias, lymphomas, and solid tumors	Increased alpha fetoprotein; sensitivity to ionizing radiation
Cross-link repair and homologous recombination	Fanconi anemia	Bone marrow failure, congenital anomalies, abnormal pigmentation, and increased risk of leukemias and head and neck and genitourinary malignancies	Chromosome breakage assay after exposure to diepoxybutane and/or mitomycin C
RECQ helicase disorders	Bloom syndrome	Short stature, butterfly rash on face, immunodeficiency, and increased risk of multiple cancer types	Increased sister chromatid exchange

**TABLE 42-2 Cancer Phenotype of Patients with Mismatch Repair Deficiency Syndrome**

Genes	Age of Diagnosis of 1st Tumor	Leukemia/Lymphoma—T Cell	Brain Tumors—Gliomas	HNPPC/Lynch Syndrome Tumors
<i>MSH2 MLH1</i> (n = 20)	3.5 years (0.4–35)	11	4	6
<i>MSH6 PMS2</i> (n = 5)	9 years (1–31)	16	32	35

HNPPC = hereditary non-polyposis colon cancer
